THE AMERICAN PEDIATRIC SOCIETY'S COLLECTIVE INVESTIGATION ON INFANTILE SCURVY IN NORTH AMERICA.

The subject of infantile scurvy has so recently come into prominence, and still presents so many mooted questions, especially regarding its etiology, that it was the decision of the American Pediatric Society a year ago to undertake a collective investigation of the matter, based upon the cases occurring in America. This seemed particularly needed, as no other such study upon a large number of cases has yet been made in any country.

The committee which is now making its report was accordingly appointed. It has been diligently at work during nearly a year, and has used every means in its power to reach reports of cases of the disease. A list as accurate as possible was prepared of all the medical journals of North America, and a notice of the proposed investigation was sent to each, inviting correspondence on the part of all readers. Letters were sent to the secretaries of the county societies in a large number of the States of the Union, requesting that notice be given at the meetings. Letters were also addressed to the professors of diseases of children in all the regular medical colleges of the United States. The "Index Medicus" was searched for the names of those who had published reports of cases, and letters were addressed to all of them, as indeed to all physicians of whom even the rumor had come of probable cases under their charge. Circulars were printed containing questions to be answered, and were sent to all the members of the American Pediatric Society, to all physicians applying for them, and, finally, wherever there seemed any chance of getting a response.

The questions contained in the circular requested information on the following points: Whether the case was seen in hospital or private practice; the race, sex, and age; the hygienic surroundings, family history, and previous illnesses; full details of feeding from birth, and the influence which the food appeared to have had upon the development of the disease; the symptoms in detail, with special reference to pain and its location, apparent paralysis or inability to move, swellings, fractures, hemorrhages, the condition of the gums, the presence of fever, the condition of the urine and bowels, the presence of anæmia or malnutrition and of rickets or any other complicating diseases, and the character of the first symptom to develop; the treatment in detail, with duration of illness, and the time before decided improvement was discovered; the direct cause of death in fatal cases, and the post-mortem findings; and, finally, whether the case had been published previously.

The committee has been surprised and pleased at the large number of replies received. There are other cases of which it has knowledge of which no reports could be obtained, and undoubtedly many more whose existence was not discovered. But in all the committee has collected 379 cases seen by 138 observers. Some of the cases are very incompletely reported, but in the majority of instances the answers are for the most part satisfactory. No cases needed to be excluded as instances of mistaken diagnosis, although a very few were somewhat doubtful.

The topics covered by the questions can best be taken up for the most part seriatim, stating merely what the reports state, without vouching for the correctness of opinions.

Race.—The race to which the subjects of the disease belong is stated in 372 cases. It is not given with definiteness sufficiently often to allow of an analysis further than to say that there were 367 white, 4 black, and 1 Chinese.

Sex.—Sex shows out of 372 cases, 189 male, *i.e.*, 51 per cent.; and 183 female, *i.e.*, 49 per cent.; a difference not decided enough to indicate that sex is an etiological factor. In the remaining cases the sex is not mentioned.

Age.—Age is a very important matter. Although, strictly speaking, the age of the cases of infantile scurvy should be limited to those under two years, the committee has ventured to include a few in children slightly or decidedly older than this; since the etiology and symptoms are not different in any respect. Question IV. on the circular reads, "Age when Seen with Scurvy," while XIV. reads, "Duration of Illness before Treatment was Commenced." By combining the answers to these two questions, the age at which the illness developed could be determined in most instances. Reliable information was given in 359 cases; in the remaining number the age was unknown or was not stated. The accompanying tabular arrangement shows the number of cases developing at different ages:

AGE WHEN SCURVY DEVELOPED.

Age.	Number of Cases.	Percentage.	Age.	Number of Cases.	Percentage.
3 weeks.	1	0.27	16 months.	7	1.70
1½ months.	1	0.27	17 "	6	1.67
2 "	3	0.83	18 "	7	1.70
3 "	2	0.55	19 "	4	1.11
4 "	9	2.50	20 "	2	0.55
5 "	5	1.40	22 "	1	0.27
6 "	13	3.62	23 "	1	0.27
7 "	33	9.19	2 years.	2	0.55
8 "	41	11.42	2 years 3 months.	1	0.27
9 "	47	13.09	2 " 6 "	1	0.27
10 "	51	14.20	2 " 7 "	1	0.27
11 "	26	7.24	2 " 8 "	1	0.27
12 "	25	7.00	3 " 6 "	1	0.27
13 "	25	7.00	4 " 2 "	1	0.27
14 "	22	6.12	6 " "	1	0.27
15 "	17	4.73	9 " "	1	0.27

It will be seen that the disease is most apt to develop between the ages of seven and fourteen months, inclusive. The youngest case was that reported by Dr. A. Matheson, of Neillsville, Wis. This was a child of four weeks, who had already been ill five days when first seen. The child was fed at the breast. Its hygienic surroundings were poor. The disease exhibited perfectly typical symptoms and ended fatally.

The oldest child, reported by Dr. J. H. Fruitnight, was one of nine years, and was also a typical case, rapidly recovering under dietetic treatment. The cause appeared to be improper diet.

[1] Reported at the tenth annual meeting, Cincinnati, June 2, 1898.

Social Position.—Of 379 cases it is interesting to note that 83 per cent. occurred in private practice, and only 17 per cent. in hospital practice. Although no absolute class distinctions can be based on these figures, yet they point very positively to the greater tendency of the disease to occur among the rich or the well-to-do. This tendency is still further illustrated by the statements of the writers regarding the hygienic surroundings of the cases. In 303 cases these are described as good, and often the statement is volunteered that they were of the very best. In 5 they were doubtful, and in only 40 are they described as bad. The figures of the report would therefore seem to indicate that the influence of bad hygienic conditions upon the etiology of the disease is extremely limited.

Previous Health.—Out of 285 cases suitable for study, it is distinctly stated in 167 that the previous health had been good. In 118 the child had suffered from various diseased conditions which may be enumerated as follows:

Bronchitis, 5; chicken-pox, 1; constipation, 1; convulsions, 3; cretinism, 1; diarrhœal conditions, 45; eczema, 1; furunculosis, 1; indigestion, 22; influenza, 6; malaria, 1; measles, 7; pneumonia, 5; rheumatism, 1; scurvy (previous attack), 1; scrofulous diathesis, 1; typhoid fever, 1; whooping-cough, 2.

It is evident that the occurrence of most of these diseases can be considered only as accidental. There is a striking preponderance of instances of digestive disturbance. This probably is an indication that the faulty diet which occasioned the scurvy produced the indigestion also. It is no proof that the digestive disease itself bore any etiological relation to the constitutional affection. This is clearly the view of the correspondents, for, in answer to the question of the circular, a belief in any other cause than diet is expressed in only 24 instances.

Rickets, anæmia, and malnutrition are not mentioned in the foregoing list. They will be referred to later.

Attention may be called to the instance of a second attack of scurvy reported by Dr. L. E. Holt. The child was eighteen months of age at the time of the second attack, the previous one having developed four months before. The first attack followed the use of Mellin's food and sterilized milk. Recovery followed in a week upon a diet of sterilized milk and beef juice, no fruit juice being given. The second attack followed the use of Reed & Carnrick's soluble food. The patient in this attack was in a wretched condition and died in eight days.

The case of scurvy developing in a cretin, reported by Dr. A. Caillé, is also interesting. The child was a typical cretin of fourteen months. Scurvy followed the use of condensed milk. Recovery was very prompt under the administration of sterilized milk, fruit juice, and cereals.

Family History.—This, too, appears to exert little or no influence. In 129 cases the family history is stated to have been good, and in 97 it is negative. In 74 the following diseases are mentioned in the family:

Alcoholism, 2; anæmia, 2; asthma, 1; carcinoma, 1; caries of spine, 1; diarrhœa, 1; eczema, 1; gout, 2; neurotic tendency, 6; paresis, 1; pneumonia, 1; rheumatism, 16; sciatica, 1; scurvy, 1; syphilis, 7; tuberculosis, 29; uricacidæmia, 1.

Diet.—The most important etiological factor, according to general opinion, is a dietetic one. Consequently, the committee has paid particular attention to this point. When correspondents did not make the matter quite clear in their answers, personal letters were addressed to them, asking for further information. A large number of such letters have been written, and replies received in most instances. Full details were asked regarding diet from birth onward, and the question of food used at the time the scurvy developed, or so shortly before that it might seem to be associated with it, was particularly emphasized. The question was also asked, whether in the opinion of each correspondent there was reason to believe that the disease depended on the nature of the food used. An affirmative answer was received in 275 cases; negative, and the disease attributed to other causes, in 24. The committee is not in a position to judge of the correctness of this view, nor can it claim that the disease did arise in any instance as the result of the diet employed. It would make merely the following statements as to the food employed at or shortly before the symptoms of scurvy were observed according to the reporters' replies.

Any accurate percentage analysis of the report is impossible, both because the correspondents have not always stated the exact nature of the food, and because in very many instances more than one form of food was given. Perhaps the following summary of some of the main divisions may be of value, it being remembered, however, that cases are repeatedly counted twice; *e.g.*, one case may be counted in the condensed-milk class and again in the sterilized-milk division.

Food Used at the Time or Shortly before Scurvy Developed.—Number of cases in which the character of the food is specified, 356.

Food given as follows:

Breast Milk.—Alone, 10; with raw milk and amylaceæ, 1; with sterilized milk and amylaceæ, 1; total, 12.

Raw Milk.—Alone, 4; with breast milk and amylaceæ, 1; total, 5.

Milk (nothing said about heating).—Alone, 8; peptonized, 4; with amylaceæ, 4; total, 16.

Sterilized Milk.—Alone, 68; with proprietary foods, 21; with amylaceæ, 8; peptonized, 10; total, 107.

Pasteurized Milk.—Alone, 16; with proprietary foods, 2; with amylaceæ, 1; peptonized, 1; total, 20.

Peptonized Milk.—Nothing further stated, 3; sterilized, 8; pasteurized, 1; with proprietary foods, 1; with amylaceæ, 1; total, 14.

Amylaceous Food (not proprietary).—Alone, 6; with breast milk, 3; with milk, 5; with sterilized milk, 8; with Pasteurized milk, 1; with peptonized milk, 1; total, 24 (9 of these were oatmeal).

Table Food.—Nothing else mentioned, 11; with condensed milk, 1; total, 12.

Mellin's Food.—Nothing further stated, 42; with condensed milk, 22; with sterilized milk, 16; with pasteurized milk, 2; with other proprietary food, 1; total, 83.

Malted Milk.—Nothing further stated, 44; with cream, 1; with amylaceæ, 1; with other proprietary foods, 2; total, 48.

Condensed Milk.—Alone, 32; with milk, 1; with cream, 1; with other proprietary foods, 3; with table food, 1; total, 38.

Reed & Carnrick's Soluble Food.—13.

Imperial Granum.—6.

Liebig's Food.—Alone, 1; with condensed milk, 1; total, 2.

Lactated Food.—Alone, 3; with condensed milk, 1; total, 4.

Nestlé's Food.—Alone, 1; with sterilized peptonized milk 1; total, 2.

Among other articles of diet mentioned by correspondents, each in one instance, are: Gardner's food, Robinson's barley, Ridge's food, Brush's food, animal broths, Bartlett's pepsinated food, Lactopræparata with malted milk.

There are a number of instances in which the writers mention "proprietary foods" without further de-

signation. In all 214 cases (60 per cent.) were fed on proprietary foods.

The effect of dietetic treatment has such an important bearing upon the etiological influence of diet that the whole matter will be discussed more fully under "Treatment."

Symptoms.—The symptoms in infantile scurvy are so typical and well known that they would appear to need little further study. Nevertheless, the attention which has been directed to them by the questions of the circular has not been without fruit.

First Symptom to Develop and Order and Time of Other Symptoms.—In response to this question the answers have not been altogether satisfactory. Undoubtedly in a large number such early symptoms as anæmia and malnutrition were overlooked or were not included by the readers as symptoms of the disease. Then in a large number, perhaps the majority of cases, the answers have not made it quite clear whether the correspondents meant that a certain number of symptoms developed in the order in which the names were written, or whether they all were noticed at one time. Presuming that the first is the writers' meaning, we make the following statement of the first symptom seen, basing this on 327 cases. The order of symptoms is too complicated and too uncertain to warrant a statistical arrangement.

First Symptoms Seen.—Pain and tenderness, 145; affection of gums, 42; interference with motion, 36; anæmia, 27; cutaneous hemorrhages, 22; swellings, 16; restlessness, 6; anorexia, 5; debility, 5; diarrhœa, 5; constipation, 2; hemorrhage from nose, 1; hemorrhage from mouth, 1; hemorrhage from rectum, 1; hæmaturia, 3; "hæmatoma of tongue," 1; irritability, 3; vomiting, 1; fever, 1; opisthotonos, 1; sweating, 1.

Pain on Motion or Handling.—Pain is clearly a very prominent symptom of the disease. Generally it is evident only when the child is moved, or tries to move itself. Sometimes it is so intense that the approach of any one to the bedside is sufficient to cause the child to scream out through fear of being touched. Pain is reported present in 314 instances. In most of the remaining no answer was made, and it is probable that the symptom could not have been a prominent one. The locality of the pain in the cases in which there were accurate details was as follows: Legs, 120; legs and arms, 25; legs and one arm, 11; legs and body, 4; one leg, 13; one leg and one arm, 1; one arm, 1; back, 1; back and legs, 1; back and leg, 1; back and thighs, 1; thighs, 1; hips and thigh, 1; one thigh, 2; one hip, 2; knees, 1; knees and ankles, 2; knees, ankles, and shoulders, 1; knees, ankles, and wrists, 2; knees and arms, 1; one knee, 1; one ankle, 1; ankles, 1; ankles and feet, 1; ankles and elbows, 1; elbow, 1.

Pain when at Rest.—In 91 cases pain seems to have been present even when the child was still; while in 134 it is definitely stated as absent under this condition.

Interference with Motion.—The symptom variously described as paralysis, pseudo-paralysis, and disability or unwillingness to move is reported frequently. It probably depends in every instance upon pain, since there is no evidence that actual paralysis occurs in the disease. In 319 cases interference with motion of this nature existed.

Rigidity is described as present in 96 cases and absent in 106. It is due to pain in most instances, but perhaps in others may have been occasioned or increased by the presence of swelling.

The parts of the body in which motion has been interfered with in any way in the cases reported, and the locality mentioned in detail, may be enumerated as follows:

Legs, 159; legs and arms, 55; legs and one arm, 14; legs and one hand, 2; one arm, 3; legs and thighs, 1; thighs, 3; one leg and one arm, 1; one leg, 27; one thigh, 2; hips, 1; one hip, 2; one hip and thigh, 1; one hip and knee, 3; hip, leg, and shoulder, 1; hip, élbow, and shoulder, 1; one knee, 4; one ankle, 2; ankles, knees, hand, and wrist, 1.

Position of the Limbs.—To a question regarding the position of the limbs, about which Barlowe speaks so definitely, there have been replies in 205 cases. In 17 of these the position was normal. In the rest we find the position of the limbs as follows:

Flexed, 152; extended, 23; flexed and abducted, 1; flexed and adducted, 1; flexed and everted, 1; abducted, 1; everted, 3; everted and extended, 2; toes extended, 1; feet extended, 3.

Weakness of the Back.—The occurrence of weakness of the back, a symptom which Barlowe says is marked, is mentioned as present in 97 of the cases reported to the committee and as absent in 108. In the remaining nothing is said of it.

Depression of the Sternum.—This condition is likewise emphasized by Barlowe as being sometimes striking and characteristic. It is mentioned in 34 cases, but said to have been absent in 170 others. It is not certain in the cases of the report how frequently the condition had developed acutely as a result of scurvy and how often it had already been produced by a previously existing rachitis.

Swellings.—The effort has been made by analyzing the cases collected to determine the position of local swellings, whether these were situated in the joints or the shafts of the limbs, in the soft tissues or in the bones, and whether any redness was present. The answers are not clear in every instance, and are frequently somewhat contradictory, partly, perhaps, from failure of the observer to understand the question, and partly from lack of careful discrimination between subperiosteal and other effusions, and between effusion into a joint and that about it. The great irregularity also of the distribution of the swelling renders an accurate tabular arrangement too complicated. Remembering that in many cases more than one part of the body was involved and that the figures given do not mean that only the portion mentioned is affected in these cases, the following division may be made:

Joints (or probably oftener about joints) involved in 165 cases. Location given in 101, viz.: Knees, 73; ankles, 28; wrists, 12; hand, 1; elbow, 3; shoulder, 5; hip, 6.

Shafts of limbs involved in 179 cases. Location given in 123, viz.: Thighs, 59; legs (below knee), 61; "legs" (not further stated), 11; forearm, 5; upper arm, 4; "arm," 5; ribs, 1; scapula, 1; ilium, 1.

The gross results of the answers regarding the tissues in which the swelling occurred give:

Swelling in soft tissues, 97.

Swelling, subperiosteal, 114.

Swelling in both situations, 16.

In 69 cases the swollen parts were reddened also. It is stated that there was no redness in 121. A more general swelling, to be classified rather as œdema, is described in 68 cases and stated to have been absent in 98.

In regard to the swelling or protrusion of one or both eyes which has been described by writers, the symptom is said to have been absent in 110 cases and present in 49. In 9 of these swelling only is mentioned, in 18 protrusion only, and in 22 both are referred to.

Gums.—The condition of the gums and mouth is one of extreme interest. In 16 cases it is distinctly stated that the gums were entirely unaffected, while in 313 they were diseased. The degree of involvement varies from slight swelling to great sponginess and even ulceration. The degree and form of the affec-

tion in the cases suitable for study may be seen in the following table:

Swelling, absent, 14; present, 293
Sponginess, absent, 27; present, 249.
Discoloration, absent, 23; present, 259.
Bleeding, absent, 64; present, 188.
Ulceration, absent, 101; present, 91.

The relation of the affection of the gums to the presence of teeth is of much interest. In nearly all the cases of scurvy in this report teeth were present, but what influence this has is not quite clear, since experience teaches that curiously it is usually the gums of the upper jaw which are most affected, although the lower teeth naturally are the first cut. Statistics on the portion of the gums involved were not furnished sufficiently to allow of conclusions; but regarding the teeth it is to be noted that of 359 cases suitable for comparison teeth had already appeared in 314 instances, *i.e.*, 87.5 per cent.; while in only 45 cases, *i.e.*, 12.5 per cent., were there no teeth. In studying more carefully these 45 cases of scurvy without teeth we may make the following analysis:

No teeth; gums normal, 21 cases.
No teeth; gums affected, 24 cases.

The conditions present in the latter group were as follows:

Swelling, 19 cases; sponginess, 14 cases; bleeding, 5 cases; discoloration, 17 cases; ulceration, 4 cases.

This is a proof that affection of the gums may occur equally well when there are no teeth as when teeth have developed. The fact that in the great majority of cases of infantile scurvy the presence of teeth and the affection of the gums are associated depends merely on the fact that the disease generally develops at an age when teeth naturally have been cut.

Cutaneous Hemorrhages.—These have occurred with frequency in the cases reported. Accurate data are given in 353 cases. Of these, cutaneous hemorrhage is reported present in 182 and absent in 171. There is much doubt about the accuracy of the writers in their classification of the hemorrhages according to size, and to the proper use by them of the descriptive names employed, inasmuch as the question on this point did not specify clearly. In 99 instances the presence of "ecchymoses" is mentioned. In 83 "purpuric eruption" is reported, and in 37 "petechiæ." In 13 the nature of the lesion is not specified.

Hemorrhage from Mucous Membranes.—Data are available in 361 cases. Of these there were no hemorrhages from any mucous membrane in 196, while in 164 they occurred. In 93 cases there was hemorrhage from the mouth. This includes the cases in which bleeding from the gums is described by writers. In 33 cases there was bleeding from the nose, in 2 from the stomach, and in 37 from the bowels. Cases of hæmaturia are not included here, and will be referred to later.

Fractures.—Fractures in infantile scurvy are usually separations of the epiphyses merely. Even these would seem to be rare, for fracture of any kind is mentioned in only 9 of our cases. In 342 it is distinctly stated to have been absent, and in the remaining the question is not answered.

Fever.—Probably in the majority of the cases of the disease upon which this report is based no temperature record has been made. In 93 cases it is stated that there was no fever; in 182 it was present, and in the remaining no answer is given. In the cases in which it was present it is described as slight in 116 instances, moderate in 23, high in 8, and irregular in 6. Clearly, fever is not a prominent symptom of the disease, and probably often, when present, depends on accidental causes.

Bowel Movements.—The following conditions are mentioned:

Bowels regular, 74.
Bowels irregular, 15.
Constipation, 126.
Diarrhœa, 65.
Bloody diarrhœa, 12.

Urine.—Judging from the number of instances in which no answers have been returned, no examination of the urine has been made in most of the cases. It is reported as examined for albumin in 163 cases; in 33 of these albuminuria is reported and in 130 it was absent. Tube casts were present in 13 instances, absent in 13, and no observation is reported in the others.

Properly speaking, the occurrence of hæmaturia should be discussed under the title of hemorrhage. It is mentioned as present in 22 cases only. Of other abnormal conditions of the urine, the following may be mentioned: Urine very acid, 1; urine scanty, 9; urine suppressed, 1; urine increased in quantity, 3; glycosuria, 1; hæmoglobinuria, 1; pus (from cystitis), 1; phosphates increased, 1; chlorides increased, 1.

Anæmia; Malnutrition.—These conditions, already referred to as often the earliest symptoms of infantile scurvy, may have been the first evidences of the disease in many of the cases on which this report is based. In other cases they must be regarded as complicating affections only. Answers are not full enough to allow of satisfactory conclusions on this point.

Anæmia is said to have been present in 254 cases, as follows:

Anæmia present (without specifying degree), 47.
Anæmia slight, 66.
Anæmia moderate, 32.
Anæmia marked, 109.

Blood examinations were made in 15 cases and the conditions noted as follows: The percentage of hæmoglobin was much reduced in all the cases, 8 in number, in which an examination was made, in some it being as low as 35 per cent. Of the 7 cases in which the red blood corpuscles were counted, all showed a reduction except 2. In these 2 the number was normal or nearly so, but the hæmoglobin was 50 and 35 per cent., respectively. Leucocytosis was present in 5 cases, poikilocytosis in 2. In only one instance was there a differential count of the leucocytes made.

Of 217 cases in which the question is answered, emaciation is recorded in 167 and is said to have been absent in 50.

Malnutrition was observed in 178 cases out of 216, in which replies were made as follows:

Malnutrition present (without specifying degree), 108; slight, 20; moderate, 7; marked, 43.

Rickets.—Infantile scurvy has so often been described as "scurvy rickets" and "acute rickets" that the investigation of the actual relationship of the two diseases was one of the matters to which the committee directed especial attention. The question upon the circular reads as follows: (*a*) "Any symptoms of rickets present? (*b*) Slight or well marked? (*c*) What relation in time of development did they bear to the scurvy?" Satisfactory answers were received in 340 cases; in 152 of these (45 per cent.), there were symptoms of rickets present, slight in 72, marked in 64, and the degree not mentioned in 16. In the remaining cases (55 per cent.), rickets is definitely stated to have been absent. With regard to the relation in time of development, it is stated in 50 cases that the rickets was first present; in 14 that it developed with the scurvy, and in 2 after it. There does not seem to be evidence, as far as this investigation teaches, that the association of rickets and scurvy is at all intimate. Very possibly the same defect in diet which produced the one produced the other also, but the rapid recovery under treatment which the scurvy underwent did not apply to the rickets. This seems to indicate only

accidental association of the two diseases; certainly not any causal relation between them.

Other Complicating Conditions.—A variety of affections are mentioned complicating scurvy in a number of cases, as follows:

Bronchitis, 5; cretinism, 1; enlargement of inguinal glands, 1; "cerebral symptoms," 1; convulsions, 1; pneumonia, 2; boils, 1; irritability, 1; vomiting, 4; eczema, 2; enuresis, 1; sweating of the head, 1; tympanites, 1; caput medusæ, 1; diaphoresis, 1; pertussis, 2; insomnia, 1; anorexia, 2; postnasal discharge, 1; measles, 1; restlessness, 1; phimosis, 1; indigestion, 2; laryngismus stridulus, 1; cystitis, 1.

Diagnosis.—The study of diagnosis has been only incidental, based upon the mistake made before the disease was recognized in certain cases. The only disease for which infantile scurvy was repeatedly taken appears to have been rheumatism. In several instances the affection of the legs was supposed to be due to sarcoma. The apparent paralytic condition has also been the cause of error in some instances.

Duration of Illness and Prognosis.—The disease is essentially chronic, its course terminating only on the institution of proper treatment. This seems to be proved by the answers contained in the circulars. To the question concerning the duration of the disease before the case came under observation, replies were received in 306 cases, of which the following analysis may be made:

Duration of Disease before Treatment was Commenced.

Days.	Cases.	Weeks.	Cases.	Months.	Cases.
2	3	1	15	1	18
3	3	2	33	2	42
5	2	3	58	3	31
8	1	4	22	4	14
9	1	5	8	5	4
10	9	6	29	6	7
24	1	7	6	7	2
		8	1	10	1
		10	3	12	1
				2½ years.	1

Intensely interesting in this connection are the replies to the next two questions: First, duration of illness after treatment was commenced; and second, duration of treatment before marked improvement was noticed. To the first question replies concerning 308 cases were received. Of course those fatal during the attack of scurvy are not included here nor those which passed from observation.

Still more striking are the answers to the second question, as to the time when marked improvement was first noticed. There are 311 cases suitable for study in this category, excluding fatal cases and those passing from observation as before. The replies are often astonishing. Nothing is more striking than the speed with which these reports show a grave constitutional disease disappearing under proper treatment. There is certainly no disease for which a more specific treatment can be said to exist. The replies to the last two questions may be conveniently stated in the following tables:

Duration of Treatment before Marked Improvement was Noticed.

Days.	Cases.	Weeks.	Cases.	Months.	Cases.
1	19	1	47	1	6
2	58	2	27	2	4
3	46	3	8	3	4
4	26	4	1		
5	19	5	1		
6	1	6	1		
7	2				
8	2				
9	1				
10	7				
12	2				

Reported as prompt recovery, 13; at once, 15; immediate, 1.

Duration of Treatment before Recovery was Complete.

Days.	Cases.	Weeks.	Cases.	Months.	Cases.
1	6	1	48	1	28
2	5	2	54	2	14
3	14	3	36	3	5
4	8	4	14	4	2
5	5	5	6	5	1
6	1	6	14	6	2
8	2	7	1	7	1
10	17			8	1
12	3			9	1
13	3				
15	2				
16	1				

Reported as immediate, 4; almost immediate, 9.

Treatment.—Not so much could be learned of the value of treatment as could be desired, on account of the fact that in nearly all cases we have a combination of diet and of medicinal measures, including the use of fruit juices, and it is impossible to determine absolutely which was the active curative agent.

Taking the cases in which treatment was effectual and which are suitable for study, the results may be stated as follows:

I. Cases recovering under treatment with drugs only (no change in diet) 0
II. Cases recovering under the use of fruit juice alone (no change in diet) 3
III. Cases recovering under the use of beef juice alone (no change in diet) 2
IV. Cases recovering under the use of beef juice and fruit juice combined, with or without drugs (no change in diet) 6
V. Cases recovering under the combined effect of change of diet, often including beef juice, and employment of fruit juice, with or without drugs 257
VI. Cases recovering under change of diet, often including beef juice, and use of drugs (no fruit juice) 20
VII. Cases recovering under change of diet alone, often including beef juice (no fruit juice) 38

These last two may be properly considered together, since there is no evidence that any treatment with drugs has an appreciable effect upon the disease. So many of the reported cases were treated with drugs alone without result before the correct diagnosis was made and other treatment instituted, that this belief is amply justified. Combining, therefore, divisions VI. and VII., and comparing the statements of the writers regarding the diet employed during treatment and that employed when the scurvy developed, we may make the following table based upon fifty-eight cases.

Again the committee would state that no claim is made that the recovery was the result of the change, but that it quotes merely the statements of the correspondents to the effcet that recovery took place after the change was made.

VI. and VII.—Recovery Following Change in Diet Alone, with or without Drugs. (No Fruit Juice Employed.)

Mellin's food to milk and beef juice 2
" " " raw milk and beef juice 1
" " " modified milk 4
" " " modified milk and beef juice 2
" " " diet and beef juice 1
" " and sterilized milk to beef juice and broths 1
" " " " " " sterilized milk and beef juice 2
" " " condensed milk to modified milk 1
" " " " " " raw milk 2
" " " sarcopeptone to fresh milk and beef juice ... 1

" " " raw milk 4
" " " diet 6
" " " raw milk and beef juice 1
" " " sterilized milk and beef juice 1
" " peptonized to raw milk and beef juice. 1

Sterilized milk to Pasteurized milk and diet	1
" " " " "	1
Pasteurized milk to raw milk	2
" " " fresh milk and beef juice	1
" " " sterilized milk and broths	1
Raw milk and amylaceæ	1
Breast milk to peptonized milk and broths	1
" " " sterilized milk	1
Lactated food to raw milk and beef juice	1
Reed & Carnrick's soluble food to modified milk	1
" " " " " " baked potato	1
" " " " " " beef juice	1
Imperial granum to raw milk and beef juice	1
Patented food to diet	1
Ridge's food to diet	1
Diet (poor) to diet (better)	2
Bartlett's pepsinated food to fresh milk	1

It must be noted with regard to this table and those following that the term "modified" milk is used very loosely by the reporters. Occasionally it is specified to be laboratory milk, but much oftener this is not the case, and we are unable to know whether the modification was done at home or not, and whether the milk was heated or not. Presumably it was pasteurized in many instances. Where the term "fresh" milk is employed in the table, we have been unable to learn by additional correspondence whether "raw" milk is meant or whether only a change from proprietary food to cow's milk is intended. The term "diet" as employed in the tables either expresses the fact that a large and varied number of different forms of diet were tried, too complicated to be detailed, or else quotes merely the statement of the writers that a change of diet was made, the original food probably being abandoned entirely unless otherwise stated.

The following table shows the food employed in divisions I., II., III., and IV., in which the diet was the same (except sometimes for the addition of beef juice) while the scurvy was developing and while it was recovering.

Recovery Following with no Change of Diet during Treatment.

I.	Treatment with drugs only	0
II.	Treatment with fruit juice only	3
	Mellin's food (milk sterilized)	1
	Sterilized milk	2
III.	Treatment with beef juice only	2
	Sterilized milk	1
	Raw milk	1
IV.	Treatment with combined beef juice and fruit juice only	6
	Sterilized milk	2
	Sterilized milk and broths	2
	" " " amylaceæ	1
	Table food	1

Division V. contains by far the largest number of cases, 257 in all. The changes in diet employed are much too complicated to be stated fully in the table. Moreover, they are of little value, since the treatment was such a composite one, viz.: change of diet combined with the use of fruit juice in every case, and often of beef juice and of drugs as well. A few of the more striking classes of cases may be selected as follows:

V.—Recovery Following Change of Diet Combined with Fruit Juice, with or without Drugs.

Condensed milk to milk, variously treated	23
Imperial granum to milk, variously treated	7
Lactopræparata to raw milk	2
Lactated food to milk	1
Reed & Carnrick's soluble food to milk, variously treated	3
Malted milk to milk, variously treated	38
Mellin's food to milk, variously treated	21
Mellin's food and condensed milk to milk, variously treated	19
Sterilized milk to fresh (probably always raw) milk	34
Sterilized milk to Pasteurized milk	4
Pasteurized milk to "fresh" or "raw" milk	9
Pasteurized milk to sterilized milk	1
Raw milk to sterilized milk	1
Breast milk to cow's milk, variously treated	6

The conclusions to be drawn from this combined study of etiology and of treatment seem justifiable only to the following extent:

(1) That the development of the disease follows in each case the prolonged employment of some diet unsuitable to the individual child, and that often a change of diet which at first thought would seem to be unsuitable may be followed by prompt recovery.

(2) That in spite of this fact regarding individual cases, the combined report of collected cases makes it probable that in these there were certain forms of diet which were particularly prone to be followed by the development of scurvy. First in point of numbers here are to be mentioned the various proprietary foods.

(3) In fine, that in general the cases reported seem to indicate that the farther a food is removed in character from the natural food of a child the more likely its use is to be followed by the development of scurvy.

Fatal Cases.—Twenty-nine of the 379 patients are reported to have died. In 2 of these, death seems to have been remote from the attack of scurvy. Of the remaining 27 the causes as enumerated by the reporters are as follows:

Exhaustion, 6; cerebral hemorrhage, 3; diarrhœa, 2; bronchitis, 2; vomiting (?), 1; convulsions, 1; pneumonia, 4; malnutrition, 1; pulmonary hemorrhage, 1; ulcer of stomach, 1; syncope and nephritis, 1; doubtful, 4.

It is difficult to determine in how many of these the scurvy itself could be held responsible for the death; probably in few if any.

Autopsies.—There have been handed in to the committee the reports of six autopsies in all, some of them only partial. The salient points of each may be enumerated as follows:

Case of Dr. A. Caillé. Child of nine months, ill about three months. Autopsy showed hemorrhagic spots on the pericardium and surface of the liver; subperiosteal hemorrhage of the long bones.

Case of Dr. L. E. Holt. Child of twelve months; ill for two months. Autopsy showed separation of the lower epiphysis from the shaft of the left femur; extensive subperiosteal hemorrhage of the left femur; subpleural hemorrhages; broncho-pneumonia.

Case of Dr. L. E. Holt. Child of thirteen months; ill about two months. Autopsy showed subperiosteal hemorrhage and separation of the lower epiphysis of the left femur; hemorrhages into the muscles of the left thigh, swellings about the opposite knee and both ankles; knee-joints normal; minute subpleural hemorrhages; well-marked exudative nephritis; minute hemorrhages on the surface of the liver.

Case of W. P. Northrup. (The first autopsy in the United States.) Child of eighteen months; ill about one month. Autopsy showed subperiosteal hemorrhage of both tibiæ and both femora; detachment of lower epiphysis of left femur and maceration of lower end of shaft; broncho-pneumonia of left lung; no rachitic or syphilitic changes on microscopical examination.

Case of Dr. L. Starr. Child thirteen months; ill for three months. Autopsy showed "right leg from knee to ankle stuffed with a puffy mass replacing normal tissue. Separation of both bones one inch above ankle."

Case of Dr. C. W. Townsend. Child of ten months; ill three to four weeks. Autopsy showed bloody serum in pleural cavity; perforating ulcer of the stomach; tuberculous (?) process in peritoneum.

In conclusion the committee would thank publicly their correspondents who have sent their reports of cases. They are also much indebted to Dr. William Schleif, of Philadelphia, for valuable aid in analyzing the circulars received and tabulating the results.

Committee.

THE ORGANIZATION OF THE SURGICAL PERSONNEL OF AN ARMY DIVISION (TWELVE THOUSAND MEN), AND ITS DUTIES IN TIME OF WAR.

By PAUL RICHARD BROWN, M.D.,
MAJOR, U. S. ARMY (RETIRED), ITHACA, N. Y.

THERE can be no doubt that the present regulations of the United States army furnish little information in regard to the employment of its surgical personnel in time of war. As to the organization and duties of this personnel under these circumstances, it would seem as if it almost entirely depended upon the personal ideas of the surgeons attached to the various commands. In the United States army regulations of 1895 (those now in use), nothing whatever can be found bearing upon this subject, save possibly two paragraphs.

The paragraphs in question are: Paragraph 1,412, which reads: "There will be in each company four privates designated for instruction as litter bearers, etc.," and paragraph 1,420 which says: "In field service troops will be accompanied by such number of men of the hospital corps as may be determined by the post commander, on the recommendation of the surgeon." Possibly since the present war commenced there may have been some orders or circulars issued in reference to this subject, but, if so, I am unaware of the fact.

The above paragraphs are practically all that can be found in the regulations relative to the employment of the surgical personnel of our army outside the limits of a military garrison, and even these regulations are virtually applicable to the army only on a peace footing. In the armies of all civilized nations, with the exception of our own, the number of the surgical personnel, its organization, and its duties in time of war, are fixed by regulation. Even little Japan has a thoroughly organized and equipped sanitary organization in its army, which proved itself to be of very great value in its war with China. Such orders and regulations are exceedingly essential, as otherwise there would be an entire lack of uniformity in the sanitary organization of an army, and this lack of uniformity would inevitably cause a vast amount of friction and in some cases might even result in serious injury to its sick and wounded. During my service I should have been very much at a loss to reply if, at any time, I had been suddenly asked to state what should be the number of the surgical personnel of an army of twelve thousand men, how should this personnel be organized, and what would be its duties upon the field of battle.

In the battles of the past the surgical personnel of the armies engaged has very frequently found itself entirely inadequate to cope with the emergency of the moment, and, as it has been in the past, it will undoubtedly be in the future; we can only hope to provide for a probable average of casualties of the force engaged. During our civil war the casualties of the Federal forces in battle (not including the missing) averaged about ten per cent.

This average has been obtained by taking the number of killed and wounded in twenty-eight of the principal battles and comparing it with the number of men engaged. Of course there were exceptional cases in which the percentage of casualties was very much greater; for instance, at Murfreesboro the losses were twenty-six per cent., at Gettysburg twenty-three per cent., at Gaines' Mills and Antietam twenty-two per cent. of the Federal forces. It would be utterly impossible for the surgical personnel of any army to care quickly for the necessities of such an immense number of wounded men. The introduction of the small-calibre rifle firing a bullet which has so great a range and such a tremendous initial velocity also unquestionably adds many complications to the problem which the surgical personnel of armies will be required to solve. In addition, the increased range and destructiveness of light-artillery projectiles further complicates this problem, especially so far as the location of dressing-stations and field hospitals is concerned. Dressing-stations must be located at least one thousand yards from the line of battle, and field hospitals fully two thousand yards distant; and even at these distances they will be more or less under fire. This removal of dressing-stations and field hospitals so far from the line of battle tremendously complicates the question of the transportation of the wounded to a place of succor.

It is no trifling matter to carry a wounded man something over half a mile on a hand litter, and it would be unwise to bring ambulances close to the firing-line, as it is exceedingly probable that their draught animals would be disabled before they could be loaded with wounded men. The great military surgical problem of the present day is, how shall wounded men be quickly carried from the line of battle to some point comparatively near at hand where they can receive aid and comfort?

It is to be feared that this is a problem which must remain unsolved, and that in the future, as in the past, wounded men unable to walk will be compelled to stay where they have fallen until the stress of battle is over. In all probability the employment of small-calibre projectiles will also largely increase the number of casualties (fully fifty per cent.), and it is also safe to say that the number of men killed outright will also be greatly increased on account of the marked explosive effect of these projectiles whenever they penetrate a closed cavity, such as the cranium, thorax, or abdomen.

Judging from the few statistics I have been able to obtain in regard to the percentage of killed to "hits," since the introduction of the modern rifle, I am of the opinion that of every ten men struck by modern projectiles three will be instantly killed or will die within a very short time. It may, then, be safely estimated that the casualties of a division of twelve thousand men engaged in battle with a force of nearly the same strength will be about 15 per cent. (1,800), and that 70 per cent. of this number (1,260) will require surgical attention. Of this latter number 85 per cent. (1,071) will require transportation from the line of battle to the ambulance and hospital stations: the remaining 15 per cent. will be able to reach them unassisted.

The problem which now confronts us is the transportation and care of 1,260 injured men, and what should be the number of a surgical personnel capable of accomplishing this task in a reasonable space of time. It must also be considered that a certain percentage of the personnel itself will be rendered *hors du combat* and require attention, so that all estimates must be more or less approximate. From a careful study of the organizations of foreign armies and that of our own during the civil war, I am of the opinion that the surgical personnel of a division containing 12,000 men should be a trifle over 4 per cent., less than this percentage not enabling it to cope successfully with an average number of casualties in battle.

The surgical personnel of a division (12,000 men) should then consist of 61 surgeons and 445 enlisted men, and its ambulance and transport train should consist of 40 ambulances, 16 hospital wagons, 8 medical-supply carts, and 12 pack mules. The surgical personnel of a division thus equipped will be entirely independent of the line so far as the transportation of its sick and wounded, supplies, and equipage are concerned. Assuming that a division will consist of 12 regiments divided into 4 brigades, the regiments and brigades will furnish 40 surgeons; and if we add to

this number the chief surgeon of the division we shall have 41 surgeons furnished by the command itself. To this number should be added 20 surgeons (non-regimental), who will be attached to the ambulance and hospital companies of the division. This will be at the rate of about one surgeon to every 200 men of the command, and the whole force may thus be tabulated: Division surgeon, 1; brigade surgeons, 4; regimental surgeons, 36; hospital staff surgeons, 20; total, 61. The 449 non-commissioned officers and privates of the hospital corps will be divided as follows: Two ambulance companies, each consisting of 6 hospital sergeants, 6 corporals, and 54 privates, with staff surgeon in command aided by 3 subordinates; 2 hospital companies, each consisting of 6 staff surgeons, 8 hospital sergeants, 4 corporals, and 52 privates; 73 hospital orderlies, one to each surgeon, with the exception of the junior surgeon of each regiment, who will have two to accompany him on the line of battle to give first aid, and these orderlies, with the exception of those attached to the hospital staff surgeons, will always march and mess with the regiments to which they are attached; 112 drivers (ambulance, medical-supply cart, pack mule). The whole commissioned, non-commissioned force and privates may be thus tabulated: Division surgeon, 1; brigade surgeons, 4; regimental surgeons, 36; hospital staff surgeons, 20; division orderly, 1; brigade orderlies, 4; regimental orderlies, 48; hospital staff orderlies, 20; two ambulance companies, 132; two hospital companies, 128; drivers of transportation, 112; total, 506.

In this hypothetical scheme for the organization of the surgical personnel of a division of 12,000 men, it is to be understood that on the march and in action each ambulance and hospital company will be divided into two sections, each under the command of a staff surgeon, an ambulance and a hospital section marching behind each brigade (assuming 4 brigades to the division), followed by 10 ambulances and 2 medical supply carts. The hospital wagons will follow directly in rear of the division; the 12 pack mules, one to each regiment, will be led directly behind the regiments to which they belong. During an engagement this scheme of organization contemplates that there shall be 12 regimental first-aid stations, 4 ambulance stations, and 4 hospital stations located as follows: Regimental stations will be placed as closely as practicable to the line of battle of each regiment, and the two junior surgeons of each regiment with their three orderlies will there take post, to which point the pack mules, each laden with a medical and surgical pannier, will be led. The points for the regimental aid stations will be selected by the brigade surgeons; for the ambulance and hospital stations by the chief surgeon of the division. The 4 ambulance stations, unless the terrain is particularly favorable, will be placed at least 1,000 yards to the rear of the line of battle, and the hospital stations at least 2,000 yards distant. The situation of the various stations determined, the brigade and senior regimental surgeons will take post at the ambulance stations of their respective brigades, at each of which the respective section of the ambulance company, followed by 10 ambulances and a medical-supply cart, will also take station.

As each section of an ambulance company consists of 2 surgeons and 35 men, there will be at every ambulance station 6 surgeons and 62 non-commissioned officers and men, here including brigade and regimental surgeons, ambulance and cart drivers, ambulance attendants, and orderlies. Each section of a hospital company, followed by 4 wagons and 1 medical-supply cart, will take station at the point designated for the hospital station of the brigade to which it is attached in action.

As each section of a hospital company consists of 3 surgeons and 32 enlisted men, by adding to this number the wagon and cart drivers we shall have at each hospital station 3 surgeons and 40 enlisted men. Officers of the hospital staff in charge of the ambulance companies will return to the hospital stations when their services are not required at the ambulance stations.

A statement of the functions of the surgical personnel and of its duties on the battlefield has virtually been made in stating the positions of its various components during action. The surgeons and hospital orderlies at regimental aid stations do everything practicable under the circumstances to aid the wounded; putting on tourniquets, compresses, etc. The duties of the ambulance company section at each ambulance station will be to collect the wounded and transport them to the ambulance stations on litters, where they will further be cared for and loaded into ambulances to carry them to their respective hospital stations, where all operations will be performed except those absolutely essential to prevent pain and further injury during transportation; for instance, the application of temporary dressings and splints, the administration of hypodermatic injections, etc.

At each field-hospital station, before the wounded begin to arrive, tents will have been pitched, surgical and medical chests opened, operating-tables set up, and the cooks will be preparing beef tea, hot coffee, milk, etc. As the object of this article has not been to define the duties of a sanitary organization on the field of battle except in a very general way, nothing further will be said in regard to this portion of the subject.

It will have been observed that nothing has been said in reference to the treatment of the sick and wounded of the division at other times than when actually engaged; that is, when in camp. I am of the opinion that the whole surgical personnel and equipment of the division should be concentrated in one large field hospital, with the exception of the brigade and regimental surgeons and orderlies, who remain with their regiments, and that all sick and injured men should be ordered to this hospital for treatment, except men having trifling ailments which do not incapacitate them for all duty. These men should be treated by their regimental surgeons. It will thus be seen that regimental and brigade hospitals will not be required. Each regiment will have its medical and surgical pannier carried by a pack mule, and these supplies will be amply sufficient. If a brigade or regiment is detailed for duty separately from the division to which it belongs, it should then be accompanied by a proportionate detail of the surgical personnel, ambulances, etc. It will then not be dependent upon any command to which it may chance to be attached for the care of its sick and wounded, as its surgical personnel will form part of the general surgical personnel of the command to which it then belongs.

It will probably also have been observed that nothing has been said in this article relative to the utilization of the four company bearers now prescribed by regulations for each company. I am of the opinion that they cannot be taken into consideration or relied upon in the slightest degree to render any assistance during an action. No company commander will wish to deplete his ranks while under fire, and even if he should permit his company bearers to fall out in order to carry the wounded off the field, it is altogether unlikely that they would return to the fighting-line and the company would be short four combatants and also minus its company bearers. If I am correct in my opinions in regard to the proper organization of the surgical personnel of a division, whatever

may be the size of an army, the number of its surgical personnel and the organization of this personnel can readily be determined; it is simply a question of multiplication or division.

A CASE OF PROGRESSIVE MUSCULAR DYSTROPHY (LANDOUZY-DEJERINE TYPE), WITH MICROSCOPICAL EXAMINATION OF THE STERNO-CLEIDO-MASTOID MUSCLE.[1]

By WILLIAM G. SPILLER, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE PHILADELPHIA POLYCLINIC; ASSOCIATE IN THE WILLIAM PEPPER LABORATORY OF CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA.

(From the William Pepper Laboratory of Clinical Medicine.)

ERB has classed the various forms of primary myopathy, the pseudo-hypertrophic, the juvenile of Erb,[2] the hereditary of Leyden and Möbius, and the infantile of Duchenne, of Boulogne, Landouzy and Dejerine, under the name of dystrophia muscularis progressiva—for clinically and pathologically they are one disease, with a preponderance of the lesions in different parts of the body. The pseudo-hypertrophic is a well-known form, and I need not speak of the large calves, the lordosis, the peculiar method of rising from the floor, etc. The hereditary form of Leyden and Möbius has never been distinctly separated from the other types.

Duchenne, of Boulogne, described a disease under the name of progressive muscular atrophy of childhood, which, until the time of Landouzy and Dejerine,[3] was regarded as very similar to the spinal progressive muscular atrophy of the adult. Our knowledge of the real nature of the facial (infantile) type of muscular dystrophy is due to the studies of the last two authors. In this form the facial muscles are usually involved early, and the disease begins in the first years of childhood. The orbicularis oris and orbicularis palpebrarum are wasted, and often the "tapir mouth" is seen; the child cannot whistle and a peculiar rigidity of the facial muscles is noted when the mouth is opened. The face is usually smooth, the forehead appears as if polished, the eyelids cannot be fully closed, the cheeks are atrophied, the lips are prominent, and the *facies myopathique* is so characteristic that the disease can be recognized at once. The expression of the face in laughter is most striking; the patient has the *rire en travers*—the transverse laugh; the mouth is opened laterally, but the corners are not drawn upward.

Other muscles may be affected simultaneously with the facial muscles, or later. Those especially liable to atrophy are the shoulder, arm, dorsal extensor, pelvic, and thigh muscles (Strümpell[4]). A contracture of the biceps is not uncommon. Fibrillary twitching and reaction of degeneration are rare. According to Landouzy and Dejerine, the supraspinatus and infraspinatus, the subscapularis, and the flexors of the hands and fingers usually remain intact indefinitely. Quantitative, but not qualitative, changes are noted in the electrical reactions.

In the juvenile form the muscles of the shoulders and arms are especially affected.

Two brothers of the boy I am able to present to you through the kindness of Prof. W. W. Keen, are fifteen and twenty-seven years of age respectively, and are large and apparently very muscular—almost suspiciously so, in view of the disease prevailing in the family. The only sister has very large calves: indeed, they are so large that people in the street remarked on their appearance, and she put on long dresses at an early age to escape attention. The upper extremities are small. The girl had contracture of the left sterno-cleido-mastoid muscle, but operation when she was about five years old removed the deformity, and the movements of the head are now normal. This case, therefore, presents certain features of the pseudo-hypertrophic form, with contracture of the sterno-cleido-mastoid muscle.

E. H——, a brother of the girl just described, seventeen years old, has always been weak. He had two or three severe falls when about a year old, and at this age his parents noticed that the neck was not straight and that the head was drawn to the right and downward. The torticollis, due to contracture of the right sterno-cleido-mastoid muscle, increased, and six or seven years ago became very marked. He has always had difficulty in walking, on account of muscular weakness, although he began to walk when about fourteen months old—at a later date than the other children. He has always been more feeble in the left leg than in the right. When he was four years old his mother was told by physicians that the boy was weak in all the muscles of the body. Until about four years ago he walked to school twice daily and twice home again, a distance of five or six blocks: but about four years ago he found that he became more easily tired and was unable to walk to school more than once a day.

FIG. 1.—The *Rire en Travers*. Position of the head after the sterno-cleido-mastoid was cut.

The present examination shows that the muscular atrophy is almost universal. The *facies myopathique* is well marked in the lower half of the face. When the boy laughs the *rire en travers*, described by Landouzy and Dejerine, is very evident. The corners of the mouth are drawn outward but not upward, and the muscles appear quite rigid, as though difficulty was experienced in contracting the facial muscles. The power of whistling is very limited. The lower part of the face is much wasted and the forehead is quite smooth, but the orbicularis palpebrarum contracts with normal force on each side. The shoulders, upper

[1] The clinical portion of this paper was read before the Section on General Medicine of the College of Physicians of Philadelphia, and the pathological report before the Pathological Society of Philadelphia.

[4] Strümpell: "Specielle Pathologie und Therapie," vol. iii.

extremities, trunk, buttocks, and lower extremities are all much wasted. Lordosis is not present, but distinct scoliosis is seen. The muscles of the back are not affected to the degree frequently noticed in progressive muscular dystrophy. The boy does not climb upon himself in rising from the floor, on account of the comparatively good preservation of the dorsal muscles. He rises as any normal person would do. All movements are possible and proportionate to the preservation of the muscles. The only contractures observed have been in the right sterno-cleido-mastoid and the muscles of the left calf. The hands and feet are proportionally much better preserved than other parts of the extremities, but some atrophy of the interossei of the hands is evident. Fibrillary contractions or evidences of muscular hypertrophy are not noticed anywhere.

The boy stands firmly on the right foot, but the left heel is kept elevated and only the toes and ball of the left foot are placed on the ground. In walking he limps greatly and presents the gait described by the French as the "duck walk" (*marche du canard*). Each upper limb in the middle of the arm measures 16.5 cm., and in the middle of the forearm 17.5 cm. The diameter of the chest at the nipple line is 73 cm. The right thigh in its middle portion measures 31.5 cm.; the left, 30.5 cm. The right calf in its largest portion measures 26 cm.; the left, 25.5 cm.

Fig. 2.—The position of the left lower limb resembles that seen in hip-joint dislocation.

In November, 1897, the right sterno-cleido-mastoid muscle was cut by Dr. Keen, and two centimetres of tissue were removed. At first cicatricial contraction impaired the movements of the head, but by massage the head has been straightened, and the movement is now good to the left, though somewhat hindered toward the right.

The electrical examination by Dr. J. W. McConnell showed that all the muscles of the upper extremities tested responded promptly and normally to the galvanic current. These are the biceps, triceps, brachialis anticus, supinator longus, extensors of hand and fingers, flexors of hand and fingers, and the interossei muscles.

The muscles of the lower extremities examined gave similar results. These are the tibialis anticus, extensor longus pollicis, peronei, quadriceps extensor, and the vastus internus.

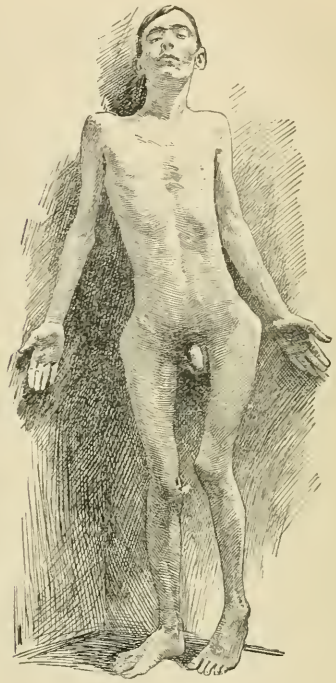

Fig. 3. The same as shown in Fig. 2.

The knee jerks are prompt but not exaggerated. The scapulæ are prominent, but the wasting in the muscles of the scapular region is not excessive, for the shoulders do not rise when the patient is lifted from the axillæ, as is not infrequently the case in the juvenile type of muscular dystrophy.

The possibility of dislocation at the left hip-joint required careful study, for at first sight one might easily have been deceived. Dr. Keen has given me the following statement: "Dr. William J. Taylor and I decided, first, that there is no typical dislocation, either iliac or otherwise. Secondly, that there is an abnormal position of the head of the bone in the left lower limb, especially when the toes are strongly rotated inward. It is as if the head of the bone was lifted out of its socket posteriorly, and I should not wonder if it were the initial stage of what hereafter will become an iliac dislocation from relaxation of the ligaments. Thirdly, that both femurs, but especially the left, are markedly rotated inwardly; when the feet are so placed that their axes are antero-posterior and parallel, both patellæ are directed inwardly. The boy tells me that he never remembers the time when his legs were not crooked, but that for the last eight or nine years they have been growing markedly worse. There is one to two centimetres' difference in the length of the lower limbs."

This condition of the left lower limb is probably

due directly to the muscular dystrophy, and the shortening seems to indicate that the bones are also affected. Very little study has been devoted to the condition of the bones in this disease, but it is reasonable to suppose that the osseous tissue is affected as well as the muscular and connective tissues. A process which causes atrophy and arrest in the development of muscles, beginning in early life, probably involves the bones as well.

Progressive muscular dystrophy seems to be a disease largely independent of the nervous system, so far as our methods of examination permit us to judge. Lesions have been found in the central nervous system in comparatively few cases. The writer has been unable to find changes in the cells of the spinal cord sufficient to explain the atrophy, in two cases of intense muscular dystrophy given to him for study by Professor Dejerine. The motor cells may possibly be less numerous, but a statement of this kind is always of very limited value, inasmuch as we have no standard of the normal number of cells. In one of these cases I was able to study the muscles.[1] It was difficult to find muscular fibres in the portions examined, as connective tissue had replaced the normal elements, and yet the small intramuscular nerve bundles and the neuro-muscular spindles were apparently perfectly normal. One of these cases had been studied clinically by Duchenne, of Boulogne.

We may recall the fact that Oppenheim and Cassirer[2] reported a case of progressive neurotic muscular atrophy, which, it is surprising to state, proved by the microscopical examination to be one of progressive muscular dystrophy.

It is impossible to understand why the nervous system is not involved in this disease, for we know well that lesions of the cells of the anterior horns produce muscular wasting early. It may be, as Erb[3] suggests, that cellular changes are present which cannot be detected. In the two cases given to me by Professor Dejerine the method of Nissl could not be employed, and I cannot deny the existence of lesions detectable by this method. At the same time we have a right to expect to find cellular changes by the carmine stain in such a chronic process, if the cause is spinal.

The muscles in the fully developed human being are certainly very closely connected with the motor nerves, and yet v. Leonowa[4] and Karl and Gustaf Petrén[5] have shown that where the spinal cord and peripheral motor fibres fail to develop in the human fœtus the muscles may be normal. This is a most extraordinary fact. The explanation which these writers give is that the motor nerves do not exert an influence on the growth of the muscles at the earliest periods of development, but do so later in life.

It seems to me that the diagnosis of progressive muscular dystrophy in this case, E. H——, may be regarded as correct. The absence of reaction of degeneration, the greater involvement of the proximal portions of the limbs, the involvement of the face (for Landouzy and Dejerine[6] say that facial atrophy in a person with general muscular atrophy, and with no symptoms of bulbar paralysis, points positively to progressive muscular dystrophy), the absence of fibrillary contractions, the preservation of the knee jerks and of sensation, the slow progress of the disease, the age of the patient, the presence of another type of muscular dystrophy in another member of the same family, the contractures of certain muscles, and the microscopical examination of the sterno-cleido-mastoid muscle to be described, make this almost a typical case of progressive muscular dystrophy of the Landouzy-Dejerine type.

The paper by Hoffmann[1] shows us how closely the myopathic forms of muscular atrophy may be simulated by the spinal, and cases of hereditary infantile bulbar paralysis are on record, and yet Hoffmann acknowledges that most cases of progressive muscular dystrophy have been shown to be without involvement of the nervous system.

The removal of the torticollis in two cases of progressive idiopathic muscular atrophy by surgical interference is a fact worthy of note.

We must, until further investigations give us reason to think otherwise, acknowledge that idiopathic muscular atrophy exists—idiopathic in the sense that the pathological changes are found only in the muscles, and that the nervous system is normal. We must separate clearly the progressive muscular dystrophy from the spinal progressive muscular atrophy, in which the wasting is due to degeneration of the cells in the anterior horns; but we must acknowledge that transitional cases also are found. It has been denied that destruction of the cells of the anterior horns occurs without involvement of the lateral motor tracts. This statement is not founded on fact. Dejerine[2] has reported two cases of atrophy of the cells of the anterior horns without degeneration of the motor tracts, and has permitted the writer to examine these specimens. Chronic anterior poliomyelitis is rare, exceedingly rare, but it does occur and may exist for years without involvement of the pyramidal tracts. Destruction of the cells of the anterior horns does not necessarily mean destruction of the central motor tracts. We may refer for further information on this subject to the thesis of J. B. Charcot,[3] to the paper by Nonne,[4] and to other communications.

The examination of the fragments of muscle removed in the case E. H—— revealed most interesting lesions. Erb[5] describes anomalies found in the muscles in cases of progressive muscular dystrophy. He found some of the muscular fibres hypertrophied and some atrophied; the muscular fibres in transverse sections were rounded and had lost their sharp angles, and some were perfectly circular. The nuclei of the muscular fibres were much more numerous, and some were situated centrally within the fibres. He found long chains of muscular nuclei, as many as twenty or forty in some fibres. He spoke of longitudinal segmentation of the muscular fibres, of such a character that one fibre formed two or three separate parts at one of its ends. He observed vacuolation of the muscular fibres, increase of connective tissue, accumulations of connective-tissue nuclei, and much lipomatous tissue. Erb believed that the multiplication of the muscular nuclei and the segmentation of the muscular fibres indicate excessive nutrition.

These changes which Erb found in progressive muscular dystrophy have been seen about tumors situated within muscles (Schäffer), and in regenerating muscles after injuries, burns, etc. (Nauwerck). Hitzig has found all these anomalies of the muscles in infantile spinal paralysis (cited by Erb).

The distinctions which have been sharply drawn

between "degenerative" and "simple" muscular atrophy are not reliable, as has been so well demonstrated by Hoffmann[1] and others. The histological investigation of the muscles, as shown by these writers, cannot determine the spinal or myopathic nature of the atrophy.

In the case E. H——, I have found considerable increase of the connective tissue. The muscular fibres in some places are much fewer than is normal, and

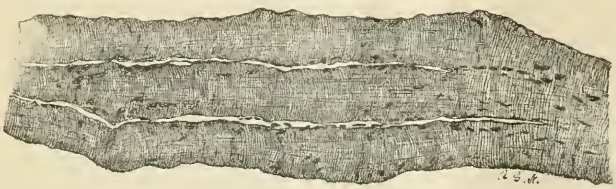

Fig. 4. Longitudinal Segmentation of a Muscle Fibre.

are circular in transverse sections; they contain many nuclei, and some also many centrally located nuclei, each surrounded by a clear space. Some of the muscular fibres are distinctly forked in longitudinal section, so as to terminate in two or three distinct fibres, each transversely and longitudinally striated, and containing nuclei. Other muscular fibres in transverse sections may be found divided into two to five distinct divisions. Long chains of rectangular nuclei are found in longitudinal fibres, and sometimes two or three chains are present within a fibre. These nuclei are shorter than most muscular nuclei; are arranged at equal distance from one another, frequently with their long axes pointing in the direction of the fibre; and may number twenty or more in a fibre. The appearance presented by these long chains is most striking. Some of the fibres have undergone hyaline degeneration.

The situation of nuclei within the centre of the muscular fibre is abnormal. Koelliker[2] says that the round or elongated nuclei in man, except in the heart muscle, are situated on the inner surface of the sarcolemma. Golgi (quoted by Morpurgo and Bindi) observed nuclei within the muscular fibres in adult man, but he regarded them as very different from the sarco-

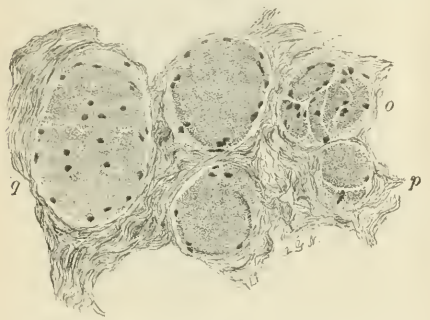

Fig. 6.—The muscle fibres are rounded in transverse section. At q a number of centrally located nuclei are seen. At o is a muscle fibre which has separated into five parts, and at p one which has separated into two parts. The connective tissue is increased in amount.

lemma nuclei. They were especially numerous near the tendons, while rare in the remainder of the muscular substance.

Dejerine and Sottas[3] observed centrally situated muscular nuclei, as well as the long nuclear chains, within the fibres in the only case of Thomsen's disease which has ever been examined post mortem. The writer has been allowed the privilege of examining these sections also.

Morpurgo and Bindi[1] have studied the muscles of an eight months' human fœtus and of adult man. The muscular fibres are of more equal size and smaller in the fœtus, and the number of nuclei in the different fibres is nearly the same. In adult human muscles of fine calibre (the external muscles of the eyeballs, the zygomaticus major), the nuclei in the smaller fibres are about as numerous as in the fibres of the same calibre in the fœtus, but as the fibres are longer the total number of nuclei in each fibre must also be greater.

The smaller the fibre the thicker are the nuclei, and the latter becomes less numerous with the growth of the muscular fibre. In hypertrophy due to activity the small fibres grow more rapidly than the larger, and their relative excess of nuclei is indicative of reserved growth force.

It may be, therefore, that the many nuclei found within the muscular fibres in the case E. H—— are indicative of the possibilities of growth of the muscle, though the anomalies are clearly those described by

Fig. —Chain of Nuclei within a Muscle Fibre.

Erb as existing in progressive muscular dystrophy, and the disease is a degenerative one.

It would be unjustifiable to regard these findings as pathognomonic of primary muscular atrophy; indeed, Erb himself, as already stated, by no means excludes all functional involvement of the spinal cord in this disease.

The investigations of Müller, Schultze, and especially of Dejerine have shown that hypertrophy of individual muscular fibres cannot be regarded as pathognomonic of idiopathic muscular atrophy, although at one time this view was quite generally held; and the studies of Hitzig, already mentioned, in which all of Erb's findings in muscular dystrophy are described by Hitzig as existing in infantile spinal paralysis, would warn us against making a similar mistake.

The existence of these remarkable findings in the muscles from a case of congenital or early arrest of muscular development attended with atrophy does not justify us, according to Erb, in assuming that the nervous system is not involved in such arrest. It is true that they are not seen after experimental section of nerve fibres, or after total destruction of the spinal trophic centres. In these cases hypertrophy of the fibres, vacuolation, segmentation, etc., are absent (Erb). Destruction of certain nerve cells in the anterior horns of the cord in anterior poliomyelitis may lead to alteration of nutrition in the muscles, and secondarily to the production of the muscular changes described (Hitzig, Erb); and partial congenital arrest in the development of the spinal cord could in this way be the cause of the condition of the muscles in congenital or early infantile progressive muscular dystrophy.

STATE MEDICINE.[1]

By HARRY S. PEARSE, M.D.,

CLINICAL ASSISTANT IN MEDICINE, ALBANY MEDICAL COLLEGE, ALBANY, N. Y.

STATE or public medicine is a comparatively new ramification of the science of medicine. It is a product of the last half-century and the outgrowth of several of the existing conditions of that period: First, the high plane of civilization; second, the constant and rapid advances in the science of the control of disease by sanitation and the application of new discoveries in the prevention and treatment of disease; and third, the necessity which has developed for the enactment of laws to obtain for the masses the benefits of this advanced science and civilization, and to minimize the evils which must unfortunately attend every progressive movement. The demand for legal regulation and governmental institutions of control increases in proportion to the progress of scientific knowledge and the complexity of social organization. Individuals and classes alike must be protected, restricted, and directed, as the occasion demands, by a supreme authority. Hence the demand for medical legislation.

The science of medicine, on account of its numerous branches and direct bearings upon the masses, is being subjected more and more to legal control, particularly those subdivisions which come under the head of public medicine. The more important of these subdivisions are the boards of health, State and municipal; State control of the insane; the regulation of maritime quarantine, national and State; and the State regulation of the practice of medicine. Under these heads come the control of water supplies of cities and towns, garbage and sewage disposal, drainage, sanitary plumbing, quarantine of contagious diseases, fumigation, regulation of the manufacture and sale of animal serums, registration of vital statistics, inspection of milk and food stuffs, inspection of dairies and cattle, and many other details too numerous to name.

As early as the twelfth century there was inaugurated a system of detention of vessels in Venice, as a result of the great commercial losses attending the frequent epidemics. Then commercial interests always dominated. To-day, humanitarian interests are as influential as the commercial. In fact, we may truthfully say that the humanitarian interests predominate. At the present time in the general discussion following a serious epidemic, the attending financial losses receive weighty consideration, but the great question is: "How can a recurrence of this suffering and loss of life be prevented?" And what has brought about this change? Primarily, the development of the finer instincts of human nature, with a higher regard for life and accompanying the march of civilization a horror of human suffering; and secondarily, the fact that the new science of preventive medicine has furnished the means by which thousands of lives may be saved and a large amount of suffering averted.

State medicine began in England in the forties, when the first laws were made and English sanitary control commenced. About the same time, in 1849, the initial move was made in the United States in Massachusetts; and in 1869, twenty years later, this State established her first health board. Louisiana, however, has the honor of having created, in 1865, the first State board of health in the United States. At present there are thirty-nine State health boards, and thousands of city, village, and town boards. This shows how rapid has been the movement. In no other branch of the science of medicine has the impetus been so great, and to quote Dr. Gihon: "The ascendency of hygiene has greatened and glorified medicine without dimming the lustre of any other branch."

[1] Read before the Albany County Medical Society, April 13, 1898.

Bacteriology and chemistry have followed closely, and in themselves been the chief factors in promoting the practical side of preventive medicine.

Few can appreciate the magnitude to which this science has grown in its brief existence. The details of its workings are manifold, and it has reached that point where one man cannot grasp the entire science but must confine himself to one field; as a result he becomes an expert, and the character of his work raises the scientific standard of his section and of the science as a whole. Public medicine is based on the studies of hydrology, physical geography, balneology, meteorology, bacteriology, chemistry, pestilential diseases, and prophylactic, sanitary, and legal medicine. It would be folly for one man to attempt to master all, quite as much so as for him to attempt to become an expert in every section of medicine as applied in private practice.

In consequence of the rapid progress of this science one great result has been attained, especially in the United States, in the production of the general feeling of confidence in the marine quarantine service. Epidemics of diseases which are not indigenous have little chance of entrance under ordinary circumstances, and when an invasion does rarely occur it is still more rare that the culpability can be placed at the door of science. The city of New York is, I believe, the best-protected seaport city in the world against foreign infection. The gate of ingress is guarded with every possible precaution; by inspection of ships' passengers and merchandise, by fumigation and isolation when necessary, and by many other processes, all constituting a formidable barrier. Public sanitation, as it is operated by the State and municipal boards of health, constitutes a power second only to police power; and under certain conditions its authority is supreme, as in threatened or prevailing epidemics. A glimpse of its possible eventual authority is given in a short sentence in a paper read by Dr. Gihon at the first meeting of the Pan-American Medical Congress in 1893: "The sanitary inspector is destined to become the most important agent of future civic administration." These boards formulate the plans of all sewage systems, the perfection of which is so necessary to insure healthful surroundings; order the abatement of public nuisances, such as objectionable slaughter houses and miasmatic swamps; require cleanliness of public vehicles, proper sanitation and ventilation of public buildings; inspect plumbing; isolate the sufferers from contagious diseases; investigate the causes and assume the management of epidemics; and inspect school children. These duties with others which I have named are exacted of the departments of public health. Their statistical reports on the mortality rates in different diseases in various localities are complete and of the greatest value, throwing light on the vulnerable points in the organized and constant crusade against disease, and showing the gains or losses in the field of action.

Through the medium of the State and its authority, the practice of medicine has been brought to a high standard of excellence. Within nine years the educational requirements necessary to carry on, first, the study and then the practice of the science in this State have been gradually advanced, until our standard is equal to that of any State in the union and to that of many foreign countries.

This brings us to the consideration of the relations of physicians and corporate bodies of physicians and the science which they represent to the law makers. It is needless to say that within the past few years the influence of legislative enactments upon the medical world has gradually increased; for the reason, as I have said, that laws are necessary to regulate the complications which are bound to arise when a science such as medicine is a factor in the relations of the

masses to the civic administration. New complications arise year after year, requiring new laws to meet them. Now the quesiton follows: Whose judgment should be paramount in the drafting and making of these laws—the law-maker's, who, as a rule, cannot appreciate the workings of a medical law; or the physician's, whose work gives him the only practical knowledge of the effects of such a law? Unquestionably you will say the judgment of the scientist should prevail, or at least have weight in the making of laws which he, in many cases, must execute. And, again, when the laws are such that they indicate direct lines for him to walk in, within his vocation, his voice should be heard and his opinions respected.

There is no science, art, or calling which is so subjected to the invasions of pestering, malignant charlatanisms and fanaticisms as the science of medicine in its practical application. Moral sense and common sense, exercised separately or together, keep down to a degree the practices of such sophistries and deceptions as clairvoyance, mind healing, and faith cure; but it is surprising that so much ignorance and blind credulity can exist at this period. But when chicanery or malpractice imperil life, then the criminal law steps in and punishes. Some will say that every man is a free agent, as far as his own vital spark is concerned, and, if he cares to, he can sacrifice his own life or even that of a member of his family to his beliefs; but the physician is too much of a humanitarian to see life thus played fast and loose with. It is against the law and instincts of his profession; therefore he invokes the law to aid him and to punish the offender and the law responds. Thus fanaticism is held in check to a certain degree, and, indeed, about all that it is possible to do against this evil is now being done.

However, these are not the invasions which reflect upon the dignity and power of the profession; but the travelling hawkers, the quacks, the healers by manipulation, by peculiar methods, and by the laying on of hands, do reflect, and, though they are unworthy of the notice of scientific physicians, must be suppressed to protect the dignity of the profession and the interests of the people. This is done, in some cases by the interception of bills legalizing such practices, and in others by the enactment of laws controlling them.

We have yet to refer to the more vital questions and problems of the hour in which law and medicine are intimately connected: the further improvement of our national public-health system; the antivivisection movement; the placing of the medical expert system in a less ridiculous light; the midwifery evil; the dispensary abuse and other abuses equally important.

The criticism has been made by law-makers that they are unable to ascertain the opinions of practising physicians upon measures in progress of legislation which, if enacted into laws, would affect these same physicians in a decided and often unwelcome manner. The rally against a vicious measure is no greater than that against a good one, and it is the exception, not the rule, that the views of the profession are known on a proposed medical law. Some one has said that every physician should be a politician; this is questionable. But I do believe that every physician should have opinions upon vital questions of the day and express them at the proper time and in the proper place. Now, nearly every physician is a member of some representative corporate body of physicians, the resolutions of which, bearing on matters pertaining to public medicine, would have weight with and are sought by the makers of laws. It is the duty of every such body to pass resolutions of this character, through a committee or not, as it pleases, indicating its judgment and opinion. Otherwise, how is the legislator to know what the physician wants or does not want, or what is going to do the science or practice of medicine good, or what evil? Every physician could have his opinion expressed either in the majority or in the minority report of his society, as he might choose. I regret to say that the smaller societies in this State are dilatory in performing their duties in this direction. Time and again committees from the larger societies have called for the opinions of the smaller ones upon different questions at issue, and met with no response whatever. Lawyers and public men have said that the members of a body of physicians cannot agree upon anything; that they are constantly wrangling with each other, and it is never positively known how that body stands on a question, scientific or public. That is putting it pretty strongly, perhaps, but there is some truth in it, and we regret that many times this condition of affairs places the profession in a ridiculous light. The remedy to me seems simple, yet I may be too sanguine. The members of every body of men usually differ in their opinions on important questions. Physicians, like other men, sometimes have divergent opinions, but the majority rules in everything, and, no matter how bitter a discussion may be, the report of the majority shows the opinion of the greatest number. Laws are made by a majority of votes; unanimity is not necessary. Why cannot questions be settled in medical societies in like manner? I have not considered the fact that it is the obligation of every representative medical society to the civic administration to use its influence in and make known its opinions upon matters pertaining to public medicine. The inertia and silence of medical societies concerning questions relating to public health, hygiene, local or general medical laws, have led to some remarkably outspoken editorials in the medical press, roundly assailing the inactivity. Many physicians will say that they have not the time or inclination to devote themselves to public questions. That is not asked of them; but I venture to say that every physician has his opinions upon public medical questions. All that is asked of him is that he make known his views through the medium of his society; that those whose inclinations lead them into the active field may know his views and have his support. Some one must do the active work, bring to bear upon medical legislation the judgment of the physicians, and that one is at least entitled to a knowledge of the opinions and wants of those whom he represents and for whom he is working.

This is somewhat of a digression, however, and I will return to the specific problems of the day. There are two of a national character which are of great importance—the antivivisection movement and the reorganization of the national public-health system, or more correctly, perhaps, the organization of a national public-health board.

For the past two years there has been a movement on foot, represented by a bill in Congress, applying to the District of Columbia alone, designed to embarrass and obstruct scientific experiments upon living animals. The instigators and promoters of this movement are either faddists or people who have erroneous and distorted impressions of the methods of scientific research of this character, and who do not realize that if their ideas were made laws it would render almost impossible the future discovery of means to prevent and control virulent diseases. Scientific workers are now making a strong fight against the measure, and every physician in the country should participate.

The recent yellow-fever epidemic in the South reopened with vigor the question of national public-health control and there are now two bills in Congress relative thereto; one, called the Caffery bill, amplifying the present Marine Hospital system, and the other, known as the Spooner bill, creating a national depart-

ment of health, with a commissioner of health. Some of the principal medical societies and journals in the United States have declared themselves in favor of one or the other, and the discussion is general and spirited. Notwithstanding this division, it is a matter only of a few years when a public-health system, national in character and with supreme authority, will be established. Germany is at present considering the creation of a State department of medicine under a responsible minister.

The other problems mentioned have a local significance—those which we have to meet in our own State. The most important perhaps is the medical-expert question; following closely is the dispensary-abuse problem, then comes the midwifery evil. All of these are comparatively new to us, and subjects for exhaustive discussions in our medical societies. These questions came up before the recent legislature in the form of bills. They will come up again next year. In the mean time it is the duty of the physicians to form opinions upon them, and express them in their several societies in the form of resolutions, that the law-makers may not be at sea in the future as they have been in the past.

During the fifty-eight working days of the last legislature of the State of New York, one hundred and thirty-two bills relating to public medicine were introduced, an average of more than two a day. This shows to a degree the amount of annual legislation relating to one of the youngest branches of the science of medicine—a condition which exists not alone in New York State but throughout the United States, and in every advanced civilized country in the world. And the end is not yet. The constantly growing power and necessity of organized public medicine will eventually make it a public function of the executive department of every national government. Disraeli's comment on Gladstone's alleged indifference to sanitary legislation was that "the first consideration of a minister should be the health of the people." The minister or secretary of public health will occupy a position equal in power and importance to the head of any other department in every advanced country in the world. Such a time will come within the lives of most of us. So much for a science but half a century old.

1 South Hawk Street.

APOMORPHINE AND ITS USES.

By SAMUEL A. VISANSKA, Ph.G., M.D.,

PROFESSOR OF THEORY AND PRACTICE OF PHARMACY, SOUTHERN MEDICAL COLLEGE, ATLANTA, GA.

No doubt many of my readers will be surprised that I undertake to write an article on apomorphine, an alkaloid unknown to many, and rarely ever used by the medical profession. It is for this reason, as well as because of its many beneficial effects upon the human system, that I desire to bring the true merits of this very important drug before the public. Apomorphine hydrochlorate, the preparation in use, is an artificial alkaloid, prepared from either morphine or codeine. Its chemical formula is $C_{17}H_{17}NO_2$, according to the reaction:

$$\underset{\text{Morphine}}{C_{17}H_{19}NO_3} - H_2O = \underset{\text{Apomorphine}}{C_{17}H_{17}NO_2}$$

It should be kept in small, dark amber-colored vials.

The books state that apomorphine is a powerful emetic, nothing more. I shall endeavor to show further usefulness, and that while this compound is derived from morphine it is devoid of narcotic properties. The usual dose as an emetic is gr. $\frac{1}{4}$ by the mouth or $\frac{1}{20}-\frac{1}{10}$ hypodermically.

Physiological Effect.—Experiments upon animals have shown the physiological action of apomorphine to be varied, and from them we learn that the drug first excites the cerebral centres and subsequently depresses them; that in poisonous doses it causes convulsions, probably of spinal origin; that it acts as a direct muscle poison in causing paralysis; that it may increase the rapidity and force of the heart's action, and in larger doses cause its depression; that it first increases the rapidity of respiration, and afterward weakens it, death resulting from respiratory paralysis.

In man these symptoms are seldom or never observed, and clinically its most important effects are seen in its actions upon the vomiting-centre, upon the circulation, and upon the bronchial secretion. Apomorphine hydrochlorate acts as an emetic by its effects upon the vomiting-centre in the medulla only, and this is the case whether given subcutaneously or by the mouth. It is thus entitled to be considered a "systemic" or "centric" emetic.

The superiority of the drug over other emetics lies in its rapidity and certainty of action, in the relative freedom of its action from accompanying nausea and depression, in its unirritating quality if properly and freshly prepared, which renders its hypodermic administration admissible, and in its great efficiency when so given and its very important value when swallowing is impossible. Moreover, if emesis is produced by its subcutaneous administration, the gastric irritation to which other drugs owe their power as emetics is avoided. It will produce vomiting if given by the mouth, but only at the expense of a larger dose and a longer time. Upon the circulation apomorphine hydrochlorate in small or moderate doses usually produces little or no effect; exceptionally, however, after moderate doses, and not rarely if the dose is large, circulatory weakening and embarrassment follow, and caution should be observed in giving it to children and debilitated adults. The size of the dose must be judged by the attendant, who will consider the condition of the heart, respiration, etc.

Uses.—In puerperal convulsions no drug is so highly lauded as apomorphine given subcutaneously. It has almost taken the place of morphine and other narcotics, and its action here depends not upon the emetic power, but on the general relaxation of all the muscles, and I contend that as long as there is relaxation of the system a convulsion cannot take place; therefore the drug should be used when we have a case of threatened puerperal convulsion or if we arrive at the patient's bedside during one of these unsightly and distressing attacks. The dose should not be large enough to produce emesis, but just enough thoroughly to relax the system. I generally begin with gr. $\frac{1}{60}-\frac{1}{40}$ subcutaneously, and if the desired effect is not produced in thirty minutes the dose is repeated. It is useless for me to go into the further treatment of this symptom, which is so familiar to all. The point which I wish to make clear is the relaxing effect of the drug, if not pushed too far.

In epilepsy a hypodermic of apomorphine will prevent or cut short an attack, according as it is given before or during the fit. It can also be used as an antispasmodic in many other diseases.

In the treatment of tetanus, on the suggestion of Dr. Bomford, of Calcutta, doses of $\frac{1}{10}-\frac{1}{4}$ of a grain subcutaneously twice or three times a day were given, and the results were not disappointing. This same physician had a case of hiccough in a man, fifty years of age. He had suffered from it for about six months, and the acts numbered thirty to forty a minute. He had been a well-built man, but was reduced to a skeleton. He had tried a lot of native medicines without relief, and Dr. Bomford's predecessor had prescribed for him almost all the drugs of the pharmacopœia, without the slightest good. Dr. Bomford subsequently tried atropine, morphine, by the mouth and subcutaneously, bromide of potassium, camphor, chloroform,

emetics, a mustard plaster over the region of the diaphragm, and a host of other measures, without the least good effect. He then gave hypodermically $\frac{1}{4}$ gr. of apomorphine dissolved in one hundred and seven parts of water. In less than three minutes the symptoms subsided, and in five minutes more the patient vomited. He was not troubled with the symptom for two days. On the third day it returned, but was less troublesome. Another $\frac{1}{4}$ gr. was given hypodermically, causing vomiting and retching the entire day, but the hiccough never returned.

In bronchial asthma apomorphine affords almost instant relief when the attack has come on and the patient sits at an open window gasping for breath, with a feeling of constriction over the entire chest. It acts in this instance by the relaxing effect, and takes the place of morphine and other narcotics, which are so dreaded because of the habit often acquired. I am yet to hear of the apomorphine habit. Few asthmatic patients go through life without acquiring the morphine habit, and I wish to lay great stress upon the use of apomorphine in this disease.

In catarrhal laryngitis, especially the severe form, the use of apomorphine in small doses will often save the life of the little patient, and it does this by its relaxing-property and also its effect upon the mucous membranes, loosening the secretion and subsequently causing vomiting of the same.

Of all the diseases of childhood croup is one of the most distressing and calls for hasty action by the attending physician, and a hypodermic of apomorphine will do well, either as an abortive or when it is desired to rid the larynx of the thick, tenacious secretion already accumulated, and thus also preventing the operations of intubation and tracheotomy. In these cases a minute dose of apomorphine should be given; say, for a child two to four years of age, $\frac{1}{10}$–$\frac{1}{80}$ gr. hypodermically, to be repeated when necessary.

In all forms of bronchitis in which the cough is dry and secretion scanty, apomorphine is an excellent addition to the expectorant mixtures, and especially in pneumonia it takes the place of alkalies to free the secretion.

In cholera morbus a hypodermic of apomorphine will instantly rid the stomach of all irritable and undigested matter, and by giving a few tumblerfuls of hot water the stomach is thoroughly cleansed.

In poisoning of any kind, when we desire to rid the stomach instantly of its contents, nothing can take the place of a hypodermic of apomorphine given subcutaneously.

These are a few instances in which this most valuable alkaloid has given excellent results, and I trust it will be of some benefit to my readers in their practice. It should certainly take the place of all other emetics, and push ipecac, tartar emetic, mustard, etc., to the background. Every day new preparations are being thrown upon the market, and the physicians of to-day are eager to grasp them. The trouble is we are not familiar with the old drugs, for there are enough official preparations now. I think the alkaloid apomorphine has been kept in the hypodermic case, until mouldy, long enough.

6a Whitehall Street.

Henoch's Purpura.—The disease occurs much more frequently in children, and the principal symptoms are: (1) pain in and near a joint; (2) a purpuric or erythematous eruption; (3) abdominal pain accompanied by vomiting and diarrhœa; and (4) hemorrhagic nephritis. In typical cases all these symptoms are present; in other cases one or other of the symptoms may be absent. Relapses are very common.—Dreschfeld.

Therapeutic Hints.

Colic and flatulence, as evidenced by the signs of abdominal pain and also vomiting, may often disappear with regulated diet. These symptoms are usually much relieved by bicarbonate of sodium with syrup of ginger or spirits of chloroform. Bismuth, too, may be given with good effect—peppermint, caraway, or cinnamon water being useful excipients.—Donkin, "Diseases of Children," page 21.

Calcium Hypophosphite as a Hæmostatic.—Dr. Silvestri (*Gazzetta degli Ospedale*, January 2, 1898) recommends the hypophosphite of calcium as a hæmostatic. It may be employed in the form of a clyster, eight grams of the salt to two hundred grams of water, to which opium may be added, or it may be administered internally in doses of one gram every one and one-half hours, the daily quantity not to exceed eight or ten grams. The following powder is recommended:

℞ Calcii hypophosphit. . . . . 1.20 gm.
Pulv. opii . . . . . 0.01 gm.
At a dose; every two hours.

The drug has been employed in various forms of hemorrhage; *e.g.*, intestinal hemorrhage in typhoid, hæmatemesis from ulcus ventriculi, epistaxis, and very often in metrorrhagia from varied causes. The results in all instances were marked; the bleeding usually ceased before the total daily quantity was used up.—*Klinisch-therapeutische Wochenschrift*, No. 4, 1898.

Infantile Paralysis.—Use the continued current as soon as the diagnosis is made. Faradism is harmful. A current of eight or ten milliamperes is passed for ten minutes. Then interrupt and reverse the current a few times. The slightest cases will require a year's treatment; a bad case several years'. Early intervention is of the greatest importance.—Larat.

Stye.—At first warm compresses of lead lotion (a one-per-cent. solution of the neutral subacetate), or of alum lotion (four grains to the ounce of water), may be used. When the stye has begun to point, a small opening is made in the long direction of the lid margin. When inflammation has subsided:

℞ Ung. hydrarg. nitratis. . . . . ʒ ss.
Vaselini albi. . . . . ʒ ss.
Apply morning and night.

—Berry, *Edinburgh Medical Journal*, January, 1898.

Constipation of muscular origin in women, resulting from pregnancy and implicating the abdominal and perineal muscles, should not be treated by purgatives. Symmetrical massage and gymnastic exercises are called for. The diagnosis is made by observing the feeble abdominal constriction.—Pineus.

Tinea Sycosis.—A mild soap with warm water is first used to remove the crusts, and this is to be followed by an efficient shampoo with spirits of green soap. The infected surface of the chin and face should then be cleanly shaved, and the oil of sweet almonds thoroughly applied, for the purpose of rendering the skin soft and pliable. If after earnest effort has been made to avoid epilation no improvement has taken place, epilation may be practised. After removing the oil with warm water and a mild soap—mild potash soap is excellent—an ointment containing one of the parasiticides should be lightly but thoroughly applied. A benzoated oxide-of-zinc ointment, containing salicylic acid, fifteen grains to the ounce, is good; or two drachms of sulphur may be added also. Beta-naphthol, ten grains, with a scruple of sulphur to the ounce of oxide-of-zinc ointment is another formula.—Dr. M. H. Sears, *The Colorado Medical Journal*, December, 1897.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 2, 1898.

PENETRATING WOUNDS OF THE ABDOMEN.

THE interest in this subject is perennial and deep. It is not that the cases are so frequent or so often seen by any particular class of medical men, but the interest seems to rest upon the known difficulties in accurate diagnosis of the intra-abdominal condition, and upon the traditional and acknowledged difficulty of compassing a cure in cases in which any of the viscera are injured. Furthermore, the cases are just as liable to fall into the hands of the country physician, far from competent assistance, as under the care of the hospital surgeon in a large city. The kind of injury which presents the most difficulty in deciding what course to pursue is the stab or punctured wound. From time to time we see reported in the various journals cases illustrating different phases of the question of diagnosis and treatment in this class of injuries; and sometimes in addition to the mere report there are intelligent comment and suggestion, really of greater value than simple description of the operation and its technique.

We are compelled to give to the German journals a large share of the credit for this kind of comment and suggestion, and can only wish that those contributing to publications in the English language would devote themselves more to such aspects of questions upon which they write.

In Langenbeck's *Archiv fur klinische Chirurgie*, early in the current year Büdinger reported a very instructive case of a wound of the abdomen, made with a pocket knife, in which there were no symptoms of intra-abdominal injury for a week from the time the wound was received, and then all the symptoms of perforation of one of the hollow viscera suddenly developed. This course would not have been unusual in an injury due to contusion or to crushing force, but after a stab wound it required explanation.

When the patient was operated upon, an incised wound of the stomach was found, and the abdominal cavity was in the condition we should expect from such a perforation. The repair of the injury was an easy matter and recovery was prompt.

We cannot help being impressed by the remarkable fact that the wound of the stomach should have remained closed tightly enough for a week to prevent leakage, though it was about one and one-half centimetres in length, and that then in consequence of a fit of coughing or from some such cause should have been torn open. The plugging of the wound by everted mucous membrane cannot account for the closure of the orifice, and, furthermore, we do not believe that this eversion ever can protect in a wound large enough to permit the eversion.

We should ordinarily expect adhesions at the end of a week, strong enough to withstand all usual tension, and are somewhat at a loss to explain the occurrence of the symptoms at so late a date. The author of the paper we are considering believes that his case shows the longest recorded interval between the infliction of the wound and the symptoms of perforation, and we are inclined to agree with him. The fact that there is here a case in which such an interval did elapse, introduces a new element in our view of these cases, and compels us to say that we must watch a patient with a penetrating wound of the abdomen without symptoms of visceral injury for at least seven or eight days, and be prepared at any time to cope with the condition of perforation.

It is difficult to give any adequate explanation of the absence of strong peritoneal adhesions in this case, or to say why there should have been no evidences of inflammatory processes in the neighborhood of the wound in the stomach.

The immediate treatment of such a condition as we have under consideration presents more difficulty than the treatment of a bullet wound in the same region, for in the latter case we have no alternative but to explore and be ready for any surgical contingency, while in the case of the stab wound without immediate positive indication we may wait a number of hours and then be guided by developments. These cases cannot be reported and analyzed too often, and we wish that the rich store of material in American surgery could be more extensively drawn upon and elaborated. However, the American surgeon seems to be more of a worker than a writer.

SOME RECENT SUGGESTIONS IN THE TREATMENT OF SYPHILIS.

IT seems almost a matter for surprise that so little change has taken place in the treatment of syphilis during recent years. Mercury and the iodides have held the field against all competitors, although the manner of employing these drugs has from time to time undergone slight modifications. It has been predicted that the serum treatment would in time supersede older methods; still it cannot be said that we are to-day very near a realization of our hopes in this direction. The perfection of intradermic methods has done away with objections which for many years prevented an extended employment of the needle in this country, where it is now coming more and more into favor.

Among recent suggestions is that of Velander, indorsed by Hogner (*Boston Medical and Surgical Journal*, March 31, 1898). Instead of inunctions, mercurial ointment is spread upon the inside of a small pillow-case, which is suspended on alternate days over the patient's chest and back. The layer upon which the ointment is spread comes next to the skin, while the

unspread side protects the clothing. Velander's idea, advanced a number of years ago, that the good effect is obtained by the mercury becoming vaporized, is thus carried out. Ninety grains of fresh ointment is spread over the older layers each day, and after ten days a new pillowcase is substituted. The skin is to be washed each night. It is claimed that the effects are more rapidly secured and with less danger of salivation than by the older inunction method.

A novelty in the way of treatment is that advanced by Lalande (*La Presse Médicale*, March 12, 1898). The *modus operandi* is not given and the good results claimed would seem to necessitate elucidation. The horns of calves are reduced to a powder and incorporated by maceration in a one-per-cent. salt solution. Of this from fifteen to forty-five minims are injected beneath the skin once, twice, or more times a week. Specific manifestations are said to fade away rapidly under these injections—an effect which would scarcely be looked for, considering the small amounts of calcium and potassium salts such a fluid would contain.

Another recent suggestion, made by Bouveyron (*Lyon Médical*, January 9, 1898), is to employ for severe syphilis metallic iodine in larger dose than has hitherto been customary. To secure perfect solution, avoiding drugs which might form metallic combination, and to correct caustic and astringent effects, he advocates the following combination: iodine, one gram, dissolved in a sufficient quantity of iodide-of-potassium solution; glycerin, five to ten grams; citric acid, fifteen grams; syrup and distilled water, one litre. A tablespoonful daily is given to begin with, and this is gradually increased to six or eight tablespoonfuls for a daily dose, always given before meals.

The length of time now required to make sure that syphilis has been eliminated from the system makes it highly desirable that some rapidly as well as radically working method should be devised. Until this is done we must gladly welcome improvements in the way of giving drugs already in use, so as to secure the best effects.

THE PEDIATRIC SOCIETY'S COLLECTIVE INVESTIGATION.

In another column will be found the report of the collective investigation of infantile scurvy, set on foot a year ago by the American Pediatric Society. It is an interesting document in several respects, not the least of which is the additional testimony it furnishes of the often misleading character of medical statistics. It will be remembered that some statistics bearing upon the relation of alcoholism and longevity, collected by a committee of the British Medical Association several years ago, showed as plainly as figures can show that longevity is directly promoted by habits of intemperance. An equally absurd assertion, namely, that sterilized milk is more prone to cause infantile scurvy than any other single article of diet, might be supported by figures taken from the Pediatric Society's report. Thus we find that of the foods taken, unmixed with any other, by the greatest number of scorbutic children, sterilized milk comes first on the list, that condensed milk comes fourth, pasteurized milk fifth, and breast milk seventh. Of the three hundred and fifty-six children reported upon, one hundred and fifty-six, or forty-four per cent., were fed on some form of milk alone, nearly an equal number on proprietary foods alone, and the others on a mixture of milk and artificial food.

But, of course, this is not the only way in which these figures can be interpreted; indeed, they are as capable of being twisted in any direction to support the claims of the individual manufacturers as is the Bible to bolster up contradictory theological beliefs. Thus it does not at all follow that the food to which is credited the largest number of cases is necessarily the most injurious, since it might be held that it was merely the most generally employed. This is doubtless the explanation of the large proportion of cases among children fed on milk alone, since it is to be presumed that this old-fashioned food is still ahead of its younger rivals.

It is to be regretted that this report, which is evidently the result of much painstaking and praiseworthy effort on the part of the committee, does not give us something more definite as regards the relation of scurvy to infant feeding. The conservative conclusion of the committee, that "the farther a food is removed in character from the natural food of a child, the more likely its use is to be followed by the development of scurvy," is doubtless correct, but it is in danger of being disputed by some ingenious and not wholly disinterested student of the committee's statistics.

THE MORAL IMPERATIVE.

That true ethics and wise modes of conduct are not always the result of a full and presumably careful collegiate training in the schools of ancient metaphysicians, and, it may be feared, of modern philosophers, would appear to be the lesson taught by the actions of a certain instructor in a Pennsylvania college. Had more attention been really paid to the "ought," and especially to the "ought not," or, as some modern psychologists might term it, the "moral imperative," in the early training of this man, a career that at first promised much might not have been ruined.

During the past year an instructor in metaphysics and ethics, of apparently bright promise, in order to avenge what seemed to him to be an ill-founded and unreasonable dislike on the part of the president of the college, committed a series of vandal acts, and an actual crime, which have brought him within the clutches of the law. These acts consisted in boyish pranks, such as disabling the college organ, dumping the chapel hymnbooks into a well, tarring the seats of the chapel and the books of the pulpit, even going to the point of actual incendiarism in setting fire to one of the college buildings, and all of this merely to gratify a childish spite.

From the alienist's point of view the case would look much like one of persecutory delusions with consequent paranoia-like retaliation. In this case the moral imperative to right action, in itself fundamentally weak, was thwarted by a mind diseased.

THE RECENT MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

It is so well known that the Medical Record is always ahead of its contemporaries in printing the medical news of the day and reports of important meetings throughout the world, that it seems almost superfluous to remind our readers again of its pre-eminence in this respect. The report of the Denver meeting of the American Medical Association was given to our subscribers complete two weeks ago. Some other journals are still stringing it along in their columns, and it is almost pathetic to read the apology of the official journal of the association in its issue of June 25th, for its neglect promptly to print the proceedings, even of the general sessions.

News of the Week.

The Surgeon of the Rough Riders.—Dr. James R. Church, the surgeon of the Rough Riders, who distinguished himself at the battle of La Quasina, is a Washington boy and a son of the librarian of the senate. He is a graduate of Princeton in 1888, and obtained his medical degree from the Columbian University in Washington in 1893. He went to Camp Alger early in the war as a contract surgeon, but soon secured a transfer to the Rough Riders as surgeon.

The Medical Rejection of Volunteers.—Governor Voorhees, of New Jersey, recently complained to Surgeon-General Sternberg that the examining surgeons were exercising needless severity in rejecting many of the New Jersey volunteers. In reply the surgeon-general said that no especial instructions had been given the examining surgeons at Camp Voorhees, who were governed by the existing regulations relating to examination of recruits. Dr. Sternberg said he could not recommend that the standard be lowered, in view of the active field service required of the volunteer troops.

Dr. Henry P. Bowditch, of Boston, is to receive the honorary degree of D.Sc. from the University of Cambridge, when he is present at the meeting of the International Zoölogical Conference in that city in August. The other recipients of the honor will be Drs. Camillo Golgi, of Pavia; Willy Kühne, of Heidelberg; Hugo Kronecker, of Berne; and Sir William Turner, president of the British Medical Council.

The Post-Graduate Hospital has been placed at the disposal of the army and navy authorities for the care of the sick or wounded soldiers and sailors during the war. Reply has been sent to the members of the executive committe, by whom the offer was made, that their communication has been placed on file for future reference in the event of additional facilities being required for the care of sick and wounded.

Small-Pox at Fredonia.—It is reported that many cases of small-pox have been discovered at Fredonia, about forty miles from Buffalo, in this State. The disease appears to have existed there for some time, no precautions having been taken to prevent its spread.

Tenure of Office of Coroners' Physicians.—According to an opinion recently given by the assistant corporation counsel of this city, a coroner's physician is the personal appointee of the coroner and can be removed only by him, the full board of coroners having no power in the matter. The decision was given in a case arising in the borough of Queens, in which the board of coroners desired to remove one of the physicians against the will of the coroner who had appointed him.

Prof. Francesco Durante celebrated his jubilee, marking the completion of the twenty-fifth year of surgical teaching at the University of Rome, on June 5th. In commemoration of the event a work in three volumes, containing contributions by the leading Italian and a few foreign surgeons, among them Dr. W. W. Keen, will be issued.

The Ever Busy Sneak Thief.—Physicians in New York should be on the lookout for a well-dressed, clean-shaven young man, carrying a large valise and posing as an agent. He rings the door bell and, upon learning that the doctor is out, informs the attendant that he has been requested to wait. "I will at least wait a few minutes," he says, "and if the doctor does not return, I will call again in the morning." In those few minutes he manages to appropriate the most valuable books or other objects in the office or waiting-room.

The Associated Physicians of Long Island.—A society having this title was organized at Garden City, June 8, 1898, by over sixty physicians from the various parts of the island. The desirability of a more general acquaintance among the members of the profession on the island has long been recognized, and the very cordial and enthusiastic spirit shown by those present augurs well for the future. The meeting was called to order by Dr. Louis N. Lanehart, temporary chairman, with Dr. Robert J. Morrison, acting secretary. After the details of organization had been arranged, the following papers were presented and discussed: "Prognosis in Chronic Nephritis," by Dr. H. A. Fairbairn, of Brooklyn. The reader gave a short review of some of the investigations of the physiological chemist in late years, and pointed out their bearing on the treatment and prevention of this disease. "The History of a Case of Leprosy, with an Exhibition of the Lepra Bacillus," by Dr. James MacFarlane Winfield, of Brooklyn. The patient was a boy, aged fourteen years, native of Key West. The disease had existed two years before coming under the observation of Drs. Barber and Winfield. There was no history of contagion, nor had leprosy ever been in the family. The patient was under the care of his Brooklyn physicians four years, finally dying of exhaustion. The disease was a typical tubercular leprosy, and the case was of special interest on account of its being purely American. Dr. Ezra H. Wilson, of Brooklyn, presented a paper on "Immunity." On completion of the regular work of the day, the members united in an informal dinner. It was decided to hold three meetings a year—in June, October, and January

respectively. All members in good standing of the regular county societies of the island are eligible for membership. The following officers were unanimously elected: *President*, Dr. William Browning, of Kings; *First Vice-President*, Dr. Louis N. Lanehart, of Queens; *Second Vice-President*, Dr. William A. Hulse, of Suffolk; *Third Vice-President*, Dr. Charles Jewett, of Kings; *Secretary*, Dr. Robert J. Morrison, of Brooklyn; *Treasurer*, Dr. Arthur H. Terry, of Patchogue; *Historian*, Dr. Joseph H. Hunt, of Kings.

The "Relief."—The work of fitting up the army hospital ship *Relief*, formerly the *John Englis* of the Maine Steamship Line, was completed this week and the ship has sailed for Santiago de Cuba. It may be said that a more suitable purchase than the *John Englis* for the required purpose would have been nearly impossible to make. She is a new boat, but a year old, built by the Delaware Shipbuilding Company, and constructed of the finest steel, with engines and other machinery of the best quality. Her length is 280 feet; beam, 36 feet; and draught, 16 feet. The steamer is able at her fastest gait to make about sixteen knots an hour, and can easily keep up a speed of twelve knots. The equipping and alterations of the interior have been done under the personal direction of the commanding officer, Major George H. Torney, M.D., who has given much time and thought to the consideration of the difficulties to be overcome. Dr. Torney is to be congratulated on the success of the outcome of his deliberations. It was necessary in order to convert the ship to its present purpose almost wholly to demolish and then reconstruct the interior. All the staterooms on the main deck have been removed, the entire space being utilized as wards. Of these large wards there are five. One is placed on the forward end of the hurricane deck; another occupies the after end of the same deck. The officers' ward is situated on the main deck forward. The two largest wards are on the main deck and berth deck respectively, and are estimated to accommodate one hundred patients each. The ward in the after end of the main is reserved for surgical cases, the operating-room, well lighted and ventilated, communicating with it on the starboard side. This room is of course amply supplied with every kind of instrument likely to be required. The floor is tiled and can consequently be kept scrupulously clean. The walls, which are of wood, are enamelled with white paint. The operating-tables are of steel; also white enamelled. It is unnecessary to remark that the aseptic arrangements are as perfect as the peculiarities of ship construction will allow. The bunks, which are in two tiers, are of gas pipe, furnished with a woven-wire and cotton mattress. To prevent the patient falling out with the motion of the ship a wire screen is attached, and a wire crate to contain bandages, dressings, and medicines is fastened to the foot of each cot. Great care has been exercised to insure to the patients ample room, so that they may enjoy the benefit of plenty of fresh air. The cots are arranged in rows, the intervening space being sufficiently wide easily to permit the passage of a litter. The apparatus devised for hoisting or lowering the sick or wounded is especially ingenious and is calculated to effect its object with the utmost smoothness and expedition. On the forward side of the mainmast a steam boom has been fitted, by means of which the sick or wounded can be raised in cradles from the transport barge and deposited in whatever part of the ship desired. This boom will also be used for hoisting or lowering the steam launches. The bathing and lavatory arrangements are on a generous scale, and separate bath and toilet rooms are provided for convalescing patients as well as for the officers and medical staff and nurses. The floors of the bathrooms are of rubber. The isolating-ward is on the upper deck and it should be mentioned that in case of need a large number can be accommodated on the open deck, well sheltered from sun or rain by awnings. The ship is furnished with two complete *x*-ray outfits, electric fans, refrigerating-plant, a microscopic laboratory, photographic appliances, an ice-making machine, and distilling-plant. The electric power will also supply light to a seven-thousand candle power searchlight on the pilot house. There are in addition a number of portable electric lights. The medical staff have their quarters on the main deck forward, their messroom adjoining their staterooms. The members of the staff are Dr. Torney, commanding officer, under whose direction the ship will sail; Dr. Gorgas, yellow-fever expert; Dr. Gray, *x*-ray expert; Dr. Metcalfe, Dr. Hartsock, Dr. Williams, Dr. Meyers, Dr. Schultze, and Dr. Torney, Jr. Lieutenant Crabbs, of the eighth cavalry, has been selected to act as quartermaster and commissary. The nursing-staff consists of nine female and twenty-eight male nurses, who will have quarters on the berth deck. The number of patients who can be berthed with comfort on the *Relief* is about four hundred and fifty. There can be no doubt that the *Relief* is the most perfect and best-equipped hospital ship in the world, and is an advance in nearly every respect on the *Solace*. Advantage was taken of some errors in the designing and arrangement of the *Solace*, and care has been taken to avoid the same mistakes in the *Relief*. It would be idle to assert that the ideal hospital ship has yet been evolved, but at any rate America may take to herself the credit of showing the way to other nations in the movement for the proper treatment of sick and wounded sailors, and soldiers as well when they are engaged in operations near the sea or navigable rivers. That such a ship as the *Relief* is urgently needed to care for those soldiers who may be wounded or contract disease in the unhealthy climate of Cuba cannot be denied. It is not intended, however, to keep patients on board the hospital ship longer than is absolutely necessary; as quickly as is possible they will be transferred to the nearest shore hospital. Of course the *Relief* will fly the Red Cross flag.

Dum-Dum Bullets.—Professor von Bruns, who caused more or less of a sensation at the German Surgical Congress by his arraignment of the British in India for their use of what he called "inhuman bullets," has been proved to have made his charges in entire ignorance of the facts. Professor Ogston, of

Aberdeen, who was present when the paper was read, has published a statement that the bullets used by von Bruns were not Dum-Dum at all. It is asserted that the explosive effect of a bullet depends upon the extent to which it is denuded of its nickel mantle. The mantle of the Dum-Dum is absent for a distance of only two or three millimetres from the tip, but von Bruns experimented with a Mauser bullet, from which the mantle had been removed for a distance of fully a centimetre from the tip. Between the rapidly increasing spirit of commercialism and the prejudices engendered of national antipathy, the race of the German scientist seems to be approaching extinction.

In the Philippines it is said that there are about two million Chinese. Dr. Joseph F. Chan, a Chinese physician living in the United States, has a plan to convert a large number of these subjects into United States troops. To accomplish this the doctor has asked permission to enlist some two hundred Chinamen in San Francisco, who will aid him in converting his countrymen into fighters for the Stars and Stripes.

The American Medical Association.—The number of members and visitors registered at the Denver meeting of the association was nearly thirteen hundred and fifty.

The Late Dr. John Blair Gibbs.—At a meeting of the medical staff at the Demilt Dispensary, held June 17, 1898, the following resolutions were unanimously adopted:

"*Whereas*, Our late associate, Dr. John Blair Gibbs, while acting assistant surgeon in the United States navy, died on the field of battle during an attack by the enemy at Guantanamo, Cuba, on the 12th day of June, 1898; and,

"*Whereas*, As associates, we had reason to respect his professional fervor and attainments; and,

"*Whereas*, He voluntarily left a lucrative practice and a life of comparative ease in response to his country's call to arms, and was among the first to fall in the defence of his country.

"*Therefore, be it Resolved*, That by the death of Dr. Gibbs the medical profession has lost an active, conscientious member.

"*Resolved*, That we deem it a privilege to have been associated with Dr. Gibbs, whose self-abnegation and devotion to his country merit the praise of the nation.

"*Resolved*, That copies of these resolutions be forwarded to the medical press and to the family of the deceased.

"Charles H. Bushong, M.D., J. Dougal Bissell, M.D., N. G. McMaster, M.D., Frank N. Patterson, M.D., *Committee*.

Wonderful Surgery.—We have been looking for a crop of newspaper accounts of marvellous surgical operations on the battlefield or in the new hospital ships, and we have not had long to wait. The report is that "a remarkable surgical operation has been performed on the hospital ship *Olivette* by Surgeons —— and —— on Corporal ——, who was shot through the brain in Friday's battle. The top of his skull was removed, and the bullet was found embedded in the wall of the skull on the opposite side from which it entered. —— will recover." This, of course, is a slight thing and scarcely worth mentioning when the cable rates are so high. But it is good enough for a beginning.

A Medical Man in Trouble.—Several physicians in Harlem have recently been visited by a prosperous-looking man of military bearing, who claimed to be a retired army surgeon. His story was that he was short of ready money and could get none as it was after bank hours, and he would regard it as a great favor if his confrère would cash a check for him. The check was always returned as worthless. The man, who is said really to be a retired army officer, has been arrested and held for the grand jury in $300 bail.

Red Cross Work.—Miss Barton and the first Red Cross contingent arrived at Guantanamo, Cuba, on the steamer *State of Texas*, the first of this week. A large quantity of provisions, medical supplies, and clothing has been sent to Key West, where it is intended to establish a base of supplies. The supply boat, *Red Cross*, which was formerly the yacht *Admiral*, sailed on Wednesday for Key West with a large cargo of medical and surgical supplies, delicacies for the sick, pajamas, Roentgen-ray apparatus, and other necessary articles. Four surgeons, Drs. Solosso, Carbonel, Henry Sewall, and Mozart Lesser, also went on the same vessel. The ice-plant auxiliary is supplying the camps at Jacksonville and at Chickamauga with $20 worth of ice a day and is expected to send a large cargo from Maine to Cuba on a sailing-vessel, which will also carry lumber and sawdust for the construction of temporary icehouses. The uncertainty of the army movements renders it impracticable to set up a plant anywhere for the manufacture of ice. Two new division hospitals are to be opened at once at Jacksonville and Panama Park, Miami, in Florida.

The University of Vermont.—Dr. H. C. Tinkham, of Burlington, professor of surgery and anatomy at the University of Vermont, has been elected dean of the medical faculty *vice* Dr. A. P. Grinnell, who had held the office for twenty-four years.

The Plague is reported to be increasing in the southern Chinese seaports, but is rapidly declining in Bombay. The fear of an epidemic in Calcutta has given occasion to a peculiarly cruel and inane form of a practical joke. The *Medical Press* says that in that city, where the natives live in the greatest dread of compulsory preventive inoculation against plague, some would-be wags have created widespread alarm by surrounding belated pedestrians, and pretending to carry out the dreaded rite by sticking pins into their victims. A more mischievous form of practical joke, our contemporary says, could hardly be imagined, for the scare thus created might, at any moment, throw an excitable and fear-ridden population into open revolt.

The Baltimore Water Supply.—The health commissioner of Baltimore is making strenuous efforts to induce the city to establish a filtration plant, as the danger from typhoid fever (cases of which are very numerous at this time) is increasing.

In Cuba, from March, 1895, to March, 1897, yellow fever destroyed three hundred and eighteen officers and thirteen thousand soldiers, and still there are those who make light of the dangers surrounding an American army of invasion in midsummer.

Ambulance Surgeon Spaulding, of Roosevelt Hospital, had his finger nearly bitten off by a would-be suicide one day recently, thus adding to the reasons why a life on the tailboard of the emergency wagon is not always a happy one.

Koch's Alleged Discovery Regarding Malaria.—Professor Koch has returned to Berlin, and the papers are full of his wonderful discovery that Texas fever among cattle is spread through the agency of ticks and of his acute deduction therefrom that mosquitoes are the inoculators of malaria in man. It seems hardly credible that this aged theory can be put forth as the original discovery of a German bacteriologist in the year of our Lord 1898, but reports of his claim seem to be well founded.

Dr. George C. Pardee, of San Francisco, is prominently mentioned by the papers as the probable candidate of the Republican party for the governorship of California.

Don't Steal a Doctor's Wheel!—If this advice had been followed by a bicycle thief a week or two ago he would perhaps to-day be a happier man. The doctor had to walk back to his office, and reached it just in time to attend a man severely injured by falling from a wheel. Investigation showed that swift retribution had followed the thief, and it was the doctor's own wheel that had thrown him.

The Rhode Island Medical Society.—The eighty-seventh annual meeting of this society was held in Providence on June 2d, under the presidency of Dr. W. A. Gorton.

Professional Secrecy.—Suit was recently brought against the village of Oneida, N. Y., to recover $2,500 damages for a hernia and prolapsus uteri sustained by a fall due to a defective sidewalk. The case was decided against the village, and on appeal the plaintiff's physician was called to show that she had hernia before the accident, and the appeal by the village was based upon the alleged improper exclusion of that evidence. Chief Judge Parker gave the decision that a physician who is called upon to treat a patient at childbirth, and while doing so, and as a necessary incident of his investigations to enable him to act in that capacity, discovers a physical ailment in his patient, cannot be permitted to testify with respect to such ailment, notwithstanding it was a matter about which he was not consulted and for which he did not prescribe.

The Health of the Army in Cuba is reported to be good, dysentery, measles, and heat prostration being the chief of the illnesses, and only a few cases of those having as yet occurred. The camps are on high ground, the water supply is good, and the cool nights and mornings give a chance to the men to recover from the effects of the heat in the day. There has been but little rain yet in the neighborhood of Santiago, where the rainy season sets in later than it does on the north coast. A hospital has been established at Juragua, the nurses and supplies having been for some time in readiness on the transport *Iroquois*.

Yellow Fever.—The encouraging news comes from McHenry, Miss., that there have been no new cases of yellow fever there in several days, and it is hoped that no more will occur. According to a dispatch in *The Sun* from Montevideo, a quantity of Sanarelli's anti-yellow-fever serum has been sent to Cuba by order of the Spanish government.

Dr. William Kelly Simpson has been appointed instructor in laryngology in the College of Physicians and Surgeons, medical department of Columbia University, New York.

Dr. Horace Tracy Hanks, of this city, received the degree of LL.D. from Rochester University at the commencement on June 15th.

A Surgeon Court-Martialed.—An assistant surgeon in the navy, attached to the *Cincinnati*, has been sentenced to confinement for three months on the receiving-ship *Franklin* at Norfolk. He was tried by court-martial on the charge of having been neglectful in the performance of a duty to which he was assigned and of having been disrespectful to the chief surgeon of the vessel when taken to task for his neglect. The court acquitted him of the charge of negligence but found him guilty of disrespect to a superior officer.

Obituary.

WILLIAM HOWARD BAILEY, M.D., LL.D.,

ALBANY, N. Y.

Dr. William H. Bailey died at his home in Albany on June 24th, at the age of seventy-two years and six months. He was born in Bethlehem, N. Y., December 28, 1825, his father being Dr. Solomon Bailey, of that place. He received an academic education, and then entered the Albany Medical College, from which he was graduated in 1853. He began the practice of his profession in Utica, but at the end of a year he removed to Albany, where he continued to reside up to the time of his death.

Up to about ten years ago Dr. Bailey was a prominent figure in the State Medical Society. He was for ten years, from 1865, secretary of the society and was elected to the presidency in 1881, serving during a part of the period that the question of the revision of the code of ethics was agitating the profession of this State. He was also president of the Albany County Medical Society in 1870, and was for many years actively identified with the Albany Institute. He was a corresponding member of the Medico-Legal Society of New York and an honorary member of the Texas State Medical Society. The honorary degree of LL.D. was conferred upon him by the Soule University, at Galveston. In 1882 he was appointed one of the State consulting board of the Hudson River Hospital for the Insane at Poughkeepsie, which office he held for several years. He was one of the United States board of pension examining surgeons for many years, and also served as obstetrician and later as consulting obstetrician to the Albany Hospital.

Reviews and Notices.

THE ORIGIN AND SPREAD OF PANDEMIC DIPHTHERIA. A Research on the Origin and Spread of the Disease, from an International Standpoint. By ARTHUR NEWSHOLME, M.D. Lond., M.R.C.P.; Examiner in State Medicine to University of London; Medical Officer of Health, Brighton. London: Swan, Sonnenschein & Co. 1898.

THIS work is a statistical study on the spread of diphtheria, with a history of all epidemics from 1839 to 1894, in the United States, Europe, and Australasia, based on the number of deaths and not on the number of cases. The first half of the book is devoted to illustrative charts of epidemics in all the important cities of the above-mentioned countries, and in the second half the author gives conclusions derived from the tables.

From the charts we gain several interesting comparative facts, *i.e.*: In European countries, Ireland has the lowest death rate and Paris and Berlin have the highest, while the rates of our own cities, Boston, New York, and Chicago, are even higher than that of Berlin or Paris. England's highest rate is not much more than one-half the lowest rate of Massachusetts. The author gives an historical summary of diphtheria from A.D. 380 to the present time. He draws two main conclusions, viz.: 1. The disease spreads from town to town and from country to country by personal infection. 2. Climatic influences are very strong in determining epidemics. He claims that it is closely related to deficiency in rainfall, no epidemics having been known during a succession of wet years. Dry soil and low ground water also favor it.

THE DEVELOPMENT OF THE CHILD. By NATHAN OPPENHEIM, M.D., Attending Physician to Children's Department of Mt. Sinai Hospital Dispensary. New York: The Macmillan Company. 1898.

THE old adage that "blood will tell" is strongly combated in this book by the author, who believes that environment, general education, and force of example are much stronger determining elements of a child's future than any purely hereditary influences. He devotes two chapters to comparative anatomical and physiological development to show the temporary and unstable condition of a child's economy, and therefore its susceptibility to impressions. Hereditary influences, he claims, are by far too greatly modified by different social conditions and combinations through past generations to have any weight in influencing a child's character. Predisposition is as near as we can get to heredity. Following this idea throughout, the author considers the condition of the child in the primary school; his relationship to religious and legal questions, to criminology, and to institution life. He devotes a chapter to the mother's education, or, as he terms it, "The Profession of Maternity." This and the chapter on primary schools appear to us to be the best in the book, on account of their more practical treatment—the author having allowed himself to wander less into the ethical byways than in some of the other chapters. The work teaches a very wholesome lesson on the responsibility of parents and guardians, and closes to them that very convenient loophole of escape—"heredity." The ethical and sociological sides of the question are strongly brought out, but still there is much of practical value for any one.

A MANUAL OF HYGIENE AND SANITATION. By SENECA EGBERT, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; Professor of Anatomy, Physiology, and Hygiene in the Temple College; Member of the Academy of Natural Sciences of Philadelphia. Illustrated with 63 Engravings. Philadelphia and New York: Lea Brothers & Co. 1898.

THE author of this excellent little work has been well inspired in preparing it, for there is a real need for a handy book on hygiene, not so large as to repel all but the expert nor so condensed as to be of necessity superficial and imperfect. Dr. Egbert appears to have kept to the *via media* quite successfully. The chapters of the book, the titles of which show fairly well the scope of the work, are: bacteriology, the atmosphere, ventilation and heating, water, food, stimulants and beverages, personal hygiene, school hygiene, disinfection and quarantine, the removal and disposal of sewage, vital statistics, and the examination of air, water, and food.

ORTHOPÆDIC SURGERY. By JAMES E. MOORE, M.D., Professor of Orthopædia and of Clinical Surgery in the College of Medicine of the University of Minnesota, etc. Philadelphia: W. B. Saunders. 1898.

IN this work Dr. Moore has given us a book which should find its place in the library of every general practitioner. Not only is the book well arranged and clearly written, but it abounds in numerous illustrations, which are so true to nature that one has to look at them but once to carry them in the memory ever after. There have been many larger and more voluminous books written on orthopædics, but it is doubtful if there is any which will prove of greater assistance to the busy practitioner.

THE CARE OF THE SICK AT HOME AND IN THE HOSPITAL. A Handbook for Families and for Nurses. By DR. TH. BILLROTH, Professor of Surgery in Vienna, etc. Translated by Special Authority of the Author by J. BENTALL ENDEAN, London: Sampson, Low, Marston & Co., Ltd. New York: Scribner's Sons.

THIS is the fourth edition and it has been considerably revised and enlarged. It contains fifty-two illustrations, besides an excellent steel-plate portrait of the great surgeon. It is one of the most useful and entertaining books of its kind ever written.

THERAPEUTISCHES VADE MECUM DER HAUT- UND GESCHLECHTS-KRANKHEITEN. Für Practische Aerzte. Von DR. REINHOLD LEDERMANN. Berlin. 1898.

THE arrangement of this small manual is excellent. First, it treats of the various forms of medication, and of the more important remedial agents employed by the dermatologist; and, secondly, groups and classifies these drugs, often in the form of a prescription, under distinct captions. The sections on gonorrhœa and syphilis are concise and complete. The "Vade Mecum" recommends itself to the general practitioner.

PROCEEDINGS OF THE NEW YORK PATHOLOGICAL SOCIETY FOR THE YEAR 1896. Printed for the Society. 1897.

THIS report presents the usual number of interesting cases and contains several woodcut illustrations. It concludes with an instructive lecture: "On the Relationship between Inflammation and the Sundry Forms of Fibrosis," by Dr. Adami, of McGill University.

INTERNATIONAL CLINICS: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment. By Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by JUDSON DALAND, M.D. (University of Pennsylvania), Philadelphia, Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, etc.; J. MITCHELL BRUCE, M.D., F.R.C.P., London, England, Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital; and DAVID W. FINLAY, M.D., F.R.C.P., Aberdeen, Scotland, Professor of Medicine in the University of Aberdeen, etc. Volume I. April, 1898. Philadelphia: J. B. Lippincott Company.

THE volume before us quite comes up to the standard in the names of contributors and in what they have written, though the illustrations are not so numerous as is sometimes the case in the "Clinics."

To enumerate a few writers: Jaccoud, Tirard, Maylard, Marfan, Ballantyne, Hayem, Robin, Bramwell, Bridge, Ingals, Hirschfelder, McCall Anderson, Alex. James, Mathews, Montgomery, Coe, Dabney, and Daland himself. There are others, but what can one wish more?

RESEARCHES ON TUBERCULOSIS. The Weber-Parkes Prize Essay, 1897. By ARTHUR RANSOME, M.D., M.A. Cantab., F.R.S. London: Smith, Elder & Co. 1898.

IN this brochure the subject of tuberculosis is presented with extraordinary clearness and scientific precision. One cannot read too much of so common a disease, and the author's essay is certainly a most valuable contribution to the subject. The various chapters are well chosen and arranged, the style is clear and concise, and many new, important, interesting, and instructive facts are brought out in the course of the work.

Bäder-Almanach. Mittheilungen der Bäder, Luftkurorte und Heilanstalten in Deutschland, Oesterreich, der Schweiz und den angrenzenden Gebieten, für Aerzte und Heilbedürftige. Berlin: Druck und Verlag von Rudolf Mosse.

The title explains the contents. A very excellent reference book, since it contains all the necessary information as to the location, accommodations, and advantages of the various European bathing-resorts.

International Clinics: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment. By Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by Judson Daland, M.D. (University of Pennsylvania), Philadelphia; J. Mitchell Bruce, M.D., F.R.C.P., London, England; Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital; David W. Finlay, M.D., F.R.C.P., Aberdeen, Scotland. Volume IV., Seventh Series. Philadelphia: J. B. Lippincott Company.

Many interesting lectures are gathered together in this issue. Among them are: "Venesection in Heart Failure," Warner; "Treatment of Acne," Hutchins; "Diabetes," Klemperer; "Differential Diagnosis of Kidney Lesions," Heitzmann; "Diagnosis of Gastric Diseases," Boas; "Curability of Tuberculosis," Grancher; "Prevention of Tuberculosis," Eshner; "Differential Diagnosis of Typhoid," Charles L. Greene; "Localization of Paralysis," Fisher; "Operation for Fistula," Mathews; "Diagnosis of Syphilis," Andrew Clark; "Osteomyelitis," Cumston; "Fibroid," Mundé; "Contagious Impetigo," Cantrell; and many others. The work is in every way worthy of consideration.

Diseases of the Stomach: Their Special Pathology, Diagnosis, and Treatment, with Sections on Anatomy, Physiology, Analysis of Stomach Contents, Dietetics, Surgery of the Stomach, etc. In Three Parts. By John C. Hemmeter, M.B., M.D., Ph.D., Clinical Professor of Medicine at the Baltimore Medical College, Consultant to the Maryland General Hospital, etc. Philadelphia: P. Blakiston, Son & Co. 1897.

It seems to be an unquestionable fact that the human stomach has attracted to itself a degree of attention which a few decades ago it could scarcely hope for. Still surgeons would have us believe that as an organ necessary for the economy it has ceased to command serious consideration, and that its removal is attended with slight consequences. If one may judge by the number of volumes devoted to a consideration of the stomach alone, the conviction must force itself upon the mind that the importance of this particular organ is not going to suffer from lack of literary consideration. And still the subject may be said to be a new one, so far as America is concerned, and the author deserves particular credit for bringing out so clear and comprehensive a work. It is much more pretentious than any which has preceded it here, there being seven hundred and eighty-eight pages, inclusive of an excellent index. There are a number of interesting illustrations and some formulas interspersed through the pages.

Surgical Diseases of Female Generative Organs. By L. S. Pilcher, M.D. Philadelphia: J. B. Lippincott Company. 1898.

This brochure contains the results of ten years' experience in the treatment of the class of cases under consideration. In the five chapters the author has pretty well covered the surgical aspect of the subject and has handled it in a style which indicates his experience and skill. Most of the diseases of the female generative organs seem to have come under his observation, so that from reading the work we can get a good idea of surgical gynæcology. The "Prologue" contains several sentences which it might be well to read and remember.

Accident and Injury: Their Relations to Diseases of the Nervous System. By Pearce Bailey, M.D. New York: D. Appleton & Co. 1898.

In this work the author disclaims any desire to present an exhaustive treatise of the subject in hand, but wishes rather to collate and systematize to as great an extent as possible what has been reported by various observers and to amplify this when possible with what he has himself observed. In the preface due acknowledgment is made to the various writers whose works have been used as sources of material in the preparation of this volume.

The book does represent a large amount of research of a bibliographical kind, but to the specialist, under whose care most of the cases of the class under discussion will come, the extended description of methods of examination, etc., does not contain anything novel, and the man unfamiliar with such cases and methods will probably find in these descriptions a warning to consult the specialist. The chapters on injuries of the brain and spinal cord are good and contain a number of suitable figures. The chapters on such diseases as locomotor ataxia and general paralysis might have been compressed, since the connection between such diseases and the effects of trauma on the nervous system is surely not close, and could be of interest only in a question of differential diagnosis. The author has succeeded, in the chapters on traumatic neurasthenia and traumatic hysteria, in presenting the subject clearly, and those chapters with the one on malingering form decidedly the best part of the book. While this work cannot be said "to fill a long-felt want," it will undoubtedly prove useful as a handbook for those who are interested in this and cognate subjects. The indexes are good and the typographical work is very satisfactory.

Manual of Operative Surgery. By H. J. Waring, M.S., M.B., B.Sc., F.R.C.S. New York: The Macmillan, Company. 1898.

This volume is one of a useful class having the characteristics both of the larger "Text-book" or "System" and of the more compact "Compend." It is a book professedly intended for students of operative surgery, and as such is very satisfactory. The arrangement of chapters is somewhat unusual, for the first chapters, after one of an introductory nature, are devoted to abdominal surgery, a subject not generally treated of so early in such a work. The descriptions of operations are clear and the figures have the semidiagrammatic quality which is more useful in a work of this kind than any result we can get from an exact engraving or photo-mechanical reproduction.

In the chapter on hernia, the author seems to have a preference for Kocher's operation for radical cure, but his objections to Bassini's operation might not be accepted by most surgeons. No mention is made of the more recently suggested methods of avoiding the tendency to hernia after operations for the removal of the vermiform appendix. Some of the descriptions of detail at operation are somewhat tediously minute; for example, it is hardly necessary to tell a man about to operate upon a patient with a perforated gastric ulcer which side of the table to stand upon. When a man feels capable of operating on such cases, such instruction is trivial. The chapters on ligatures of arteries, nerve suture, etc., and those on bone operations cover the ground satisfactorily, and the space devoted to amputations and excision of joints is well supplied with figures. There is nothing, however, in these chapters calling for extended comment. A chapter on ophthalmic operations contains some useful general information on the subject to which the chapter is devoted.

Atlas and Essentials of Pathological Anatomy. By Dr. O. Bollinger. Volume II. Urinary Apparatus, Sexual Organs, Nervous System, and Bones. With 63 Colored Figures upon 52 Plates and 17 Illustrations in the Text. William Wood and Company. 1898.

We have had occasion before to notice the first volume of Bollinger's "Essentials of Pathological Anatomy," and the appearance of the second volume fully maintains the standard set by the first. In this volume the appearance of the lesions of the kidneys, the bladder and ureter, male and female sexual organs, mammary glands, dura mater, brain, bones, and joints are carefully and accurately portrayed. As stated in a review of the earlier volume, we believe that the work will prove of service to the practitioner who does not possess the advantages of a large library or the facilities of the hospital mortuaries of a large city.

Essays on Bacteriology and its Relation to the Progress of Medicine. By Theodore Potter, A.M., M.D., Professor of Pathology and Bacteriology in the Medical College of Indiana, Indianapolis University, Indianapolis. 1898.

The above series of essays is a popular contribution to the knowledge of bacteriology which possesses the virtue of brevity and readability. While there is nothing new or original in the essays, they make good reading for an intelligent and appreciative layman.

Medical and Surgical Reports of the Boston City Hospital. Ninth Series. Boston. 1898.

From time to time we have animadverted upon the absolute Bootlessness of most of the reports given out by the boards of health and the hospitals of this country. It is with pleasure that we notice this hospital report, which contains so much of value to the profession. In all, some twenty-one careful and well-written papers are presented, covering a wide field in both medical and surgical practice. The example set by the Boston City Hospital could be followed by others to their honor and credit.

The Genesis and Dissolution of the Faculty of Speech. A Clinical and Psychological Study of Aphasia. By Joseph Collins, M.D. Awarded the Alvarenga Prize of the College of Physicians of Philadelphia, 1897. Pp. 432. New York: The Macmillan Company.

The author has attempted an ambitious task in writing upon the disorders of the faculty of speech, for a sound discussion of the subject involves not only a thorough clinical and pathological knowledge, and an acquaintance with a vast range of literature, but also an understanding of the psychology of the day. We do not hesitate to say, at once, that Dr. Collins has shown himself a master of the problems with which he is confronted. His work is not simply the laborious compilation of a student, but represents the critical study and acumen of one who is thoroughly familiar with every detail.

The book begins with a general discussion of the disorders of intellectual expression and a brief outline of the classification which he adopts in the subsequent chapters. This classification is in the line of that generally prevalent in modern neurological literature, and the author has wisely not attempted any fine elaborations. The three great divisions which he makes are motor, sensory, and compound aphasias. The motor aphasia is subdivided into types which in general resemble what are known as cortical and subcortical aphasias and the dysarthrias. The sensory aphasias are the auditory and visual, each of which has its cortical and subcortical types. The only criticism that may be made on this is that custom does not place the dysarthrias among the aphasias. But this is an academical matter, which is not of great practical importance. The nosology of aphasia as thus given will, we trust, help to emphasize again the fact that neurologists no longer use the terms "amnesic" and "ataxic" aphasia, and that the sooner these words are forgotten, the sooner will clear ideas of the clinical pictures of aphasia be obtained by the general practitioner.

The author's introduction is followed by an interesting chapter on the history of aphasia, in which he lays emphasis on the importance of the work done by Bastian, in England, and Dejerine, in France, and in which he also emphasizes the fact that the psychological conception of aphasia taught by Charcot, and so widely disseminated by his works and his pupils, needs most serious alteration, in view of the light thrown upon the subject in recent times.

The subsequent chapters of the book are devoted to the study of the genesis and function of speech, the nature of aphasia, and then to detailed descriptions of the different types of aphasia. Finally, there are chapters upon diagnosis, etiology, morbid anatomy, and the medico-legal aspects of the subject. In these chapters are embodied several original cases, with autopsies, observed by the author himself, and all are of very positive value. Some clinical histories are also given, which illustrate in a striking way the condition of aphasic patients.

The author has much to say about the "zone of language," a comparatively recent term in localization literature, and one which deserves the prominence which is given to it. He has also a number of diagrams which illustrate very well the location of these zones and the psychological mechanism of speech. One of the points upon which the author is especially insistent is his belief that there is no centre for writing, and that the mechanism controlling this is really identical with that for articulatory speech.

Another point upon which he is equally emphatic is that all forms of aphasia are really sensory, in the sense that they are due to lesions of centres which receive stored-up impressions, rather than to lesions of centres which emit impulses. In motor aphasia, for example, the trouble is really a destruction of those sensory and memory images from which go out impulses that control the motor centres of the articulatory organs. The "motor" zone of language is always an area which is connected with the motor centres, but it is not itself a motor centre, nor are its axes connected by projection fibres passing into the motor tracts.

Still another important feature brought out by this work is the fact that there is a certain mutual relationship between the different parts of the zone of language, so that when one part is injured the whole mechanism may be for a time upset. In this way are explained the frequent and widespread disturbances of speech from lesions involving, perhaps, only a limited portion of the zone of language, such, for example, as the auditory area.

We have not space to describe further the various interesting facts which modern science has brought out in connection with the faculty of speech, and none of which seems to have escaped our author's careful scrutiny. Some criticism will perhaps be excited by a tendency to artificiality of style, and an attempt to use words which, though perhaps always proper, are at times bizarre. Despite these defects, however, the author's style is, on the whole, clear and effective. The book is well printed, in good type, upon excellent paper, in a way which is creditable to the publishers.

Die Erysipel-, Erysipeltoxin- und Serumtherapie der bösartigen Geschwülste. Von Dr. Rudolph Eschweiler, Bonn. Leipzig: C. G. Neumann. This monograph is a review of the work hitherto done in treating malignant tumors through the agency of the erysipelas coccus or its toxin. After a short history of the subject, the treatment by producing an artificial erysipelas is considered, and all reported cases are tabulated. It is shown that of twenty-two cases of inoperable sarcoma, three have been cured. Coley's method is then carefully detailed and the results are reviewed. The author states that of one hundred and sixty cases treated by this method, four cases can be considered healed. Emmerich's serum is shown to have no cures to its credit. Eschweiler concludes that the Coley injections have too rarely resulted in cures to be recommended, and considers the production of erysipelas justified. In a short appendix the method of Hericourt and Richet is described as ineffectual.

Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon at St. Thomas' Hospital, London; Surgeon to the Royal London (Moorfields) Ophthalmic Hospital. Revised and Edited by W. T. Holmes Spicer, M.A., M.B., F.R.C.S., Ophthalmic Surgeon to the Metropolitan Hospital and to the Victoria Hospital for Children. Fifth American from the Sixth English Edition. With a Supplement on Color Blindness by William Thompson, M.D., Emeritus Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. With 2 Colored Plates and 161 Engravings. Philadelphia and New York: Lea Brothers & Co. 1897.

"Good wine needs no bush," and a work that has passed through six English and five American editions does not require a very lengthy exposition of its merits at the hands of the reviewer. Those who are already familiar with the book will find that in this, as in previous revisions, the subject matter has been brought thoroughly up to date and constitutes an adequate exposition of the ophthalmological practice of to-day, while to those to whom it is new it may be said that in small compass and at moderate expense it represents an epitome of the best ophthalmology of the old and new worlds.

Etiologia e Patogenesi della Febbre Gialla, con XII. Tavole. Torino, 1897. Prof. Dott. G. Sanarelli, Direttore dell' Instituto d'Igiene Sperimentale dell' Universita di Montevideo. Turin: Rosenberg and Sellier. 1897.

Sanarelli's work on the bacillus of yellow fever is now so well known and has been so widely discussed that his published treatise of one hundred and fifty pages is opened with interest; and, it might be added, with profit, for the work shows abundant evidence of careful and painstaking work. The lithographs are excellent, though the printing and binding are of the usual bad style of Italian work.

The Anatomy and Functions of the Muscles of the Hand and of the Extensor Tendons of the Thumb. By J. Francis Walsh, M.D. (University of Pennsylvania), of Camden, N. J. Essay Awarded the Boylston Prize for 1897. Department of Anatomy and Physiology, by the Boylston Medical Committee, Boston, Mass. Pp. 51. Philadelphia: Charles H. Walsh. 1897.

The lack of conformity in descriptions of the musculature of the hand by different writers is proverbial; just how great

this variation is is well shown in the latter part of the above book, devoted to a comparison of such descriptions by most of the classic anatomists. The author's work embodies the results of the dissection of fifty-three hands, and tends to show a number of errors, as regards both character and function, in the commonly accepted accounts of the muscles in question. A bibliography and drawings add interest and value to the work.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, June 20, 1898.

GEORGE TUCKER HARRISON, M.D., PRESIDENT.

Tubal Menstruation.—DR. A. BROTHERS presented a specimen of that rare condition known as tubal menstruation. The patient, a woman of thirty-nine years, had been married thirteen and one-half years. She had had no miscarriages and had given birth to two children, the last ten years ago. During the last pregnancy she had a severe fall, as a result of which the child died, necessitating a forceps delivery ten days later. She formerly menstruated without pain, but since this last pregnancy she had had pain. For five months she suffered from pain every four weeks, but saw no blood. The cramps were sufficiently severe to confine her to bed for three or four days. Within the past year she had lost a good deal of flesh. Examination showed the uterus to be anteflexed and pushed forward by a cystic tumor in Douglas' cul-de-sac. On June 4th she was examined under ether. Only a large, bulging, cystic tumor in the posterior cul-de-sac was evident. On incision of the posterior vaginal vault and puncture of the tumor, a large quantity of dark, tarry, non-coagulated liquid escaped. A careful examination, in which he was assisted by Dr. A. Palmer Dudley, revealed extensive adhesions and a similar tumor high up on the right side. The vaginal wound was packed with iodoform gauze and an abdominal section performed, with the patient in the Trendelenburg position. During the separation of the adhesions the other sac ruptured and flooded the peritoneal cavity with the same dark fluid. The cavity was washed out thoroughly. The patient did well up to a few days ago, when the urine became highly albuminous and she developed a left-sided pleuro-pneumonia. The speaker said the case was now progressing favorably. The tumors were presented, one measuring two by two inches, and the other two by three inches. They consisted of ovarian sacs communicating with the Fallopian tubes. The latter had become agglutinated to the ovaries, and had ruptured into them. The uterine extremities of the tubes were impermeable. The uterine end of the tubes must have become narrowed at first, and then closed. Menstruation, vicarious or otherwise, must have taken place every month through the tube. This finally resulted in the blood cysts discovered at the operation. Dr. Brothers said that the specimen presented illustrated the possibility of menstrual bleeding taking place in the tubes. In a number of recorded cases the blood had been found in the tubes in connection with various forms of atresia. This was the only case, so far as he knew, in which the blood existed in the tubes without any blood in the abdominal cavity or elsewhere. It was probable that ten years ago the woman developed an endometritis and a salpingitis, and that as a result of the latter the uterine end of the tube became occluded. It would seem probable that after this the tubal mucous membrane took upon itself the menstrual function normally performed by the endometrium.

Menstruation is a Leakage from the Ovary.—DR. A. PALMER DUDLEY said that he had met with this condition only once previously in an experience covering twenty years. He had long contended that the blood of menstruation was a leakage from the ovary. With the rupture of the ovisac and the discharge of the ovum there was a leakage of blood from the ovary, as shown by the fact that in laparotomies performed at the menstrual period about two ounces of blood would be found in the peritoneal cavity. The case just reported not only illustrated this condition, but also showed what nature could do under certain circumstances to circumvent the normal function. This woman had evidently suffered from a local peritonitis, and the peritoneal covering had separated the fimbriated extremity of the tube from the general peritoneal cavity, so that an ovisac was formed and eventually became filled with blood. Each menstrual period added its portion of blood to the already distended ovisac, and, the uterine end of the tube being closed, there could be no relief in that direction. The case showed that the uterine mucous membrane was not the all-important structure in connection with the function of menstruation. It also showed that when the menstrual blood was not freely discharged, but was reabsorbed, certain reflex symptoms developed, such as neuroses and acne. In conclusion, the speaker said that menstruation was not tubal hemorrhage or uterine hemorrhage, but leakage from the ovisac.

Other Sources for the Blood.—DR. ANDREW F. CURRIER said that, while he did not question the fact of the relation of this accumulation of blood to the menstrual function, he would call attention to the fact that this was not the only way in which such an accumulation of blood might occur. For example, he had operated upon a puerperal case only two weeks ago, because of a peritonitis and the existence of two pelvic tumors. The operation revealed evidences of a recent and rather extensive peritonitis. There was an accumulation of stinking fluid in the pelvis, which was removed, and after this the appendages, which were adherent to the bottom of the pelvis, were also taken out. The tumor was found to be made up of an accumulation of fresh blood, probably in some way connected with the parturition. It seemed to him that a peritonitis fixing the tubes and ovaries was often the starting-point of the cause of such conditions. This peritonitis caused an interference with the circulation of the blood through the part. Personally he had not been able to satisfy himself regarding the fact alluded to by Dr. Dudley concerning the blood of menstruation. The bleeding seemed to him to be an episode connected with the shedding of the menstrual decidua.

The Midwifery Question.—DR. THOMAS J. HILLIS read a paper on this subject. He said that the customs or usages of ages could not be obliterated by a stroke of a governor's pen or by an act of Congress. The midwife had withstood the changes of fortune for over five thousand years, and she would continue to exist. In Greater New York about one-half of all the confinements were conducted by the midwives, or by janitresses, neighbors, and other would-be midwives. As a rule, the midwives got frightened early in a case and often summoned a physician when he was not really required. Much more injury was done by the young, meddlesome, and inexperienced medical fledglings than by the midwives. These young medicos made, on an average, about three hundred vaginal examinations, with the result that they caused congestion and drying up of the vagina, and often endangered the life of the parturient. The passing of the midwife would not mean that the parturient woman would call a physician—she would not do this even though the medical man had taken a post-graduate course in ob-

stetrics on the planet Jupiter. If these women could not have their midwives, they would employ women physicians in spite of their natural prejudices against the latter. The result of the suppression of the midwife would be that the country would be flooded with women doctors, and the medical men would be squeezed between the millstones. A much better plan than the suppression of the midwife was the determination of the individual physician to instruct properly the midwife in his neighborhood.

Qualify Trained Nurses for Obstetric Work.—Dr. Thomas H. Manley said that the government of Great Britain had just decided to register midwives. Personally he had long been of the opinion that, as a rule, a man had no business in the lying-in chamber, and that this was the special sphere of the midwife, the trained nurse, and the woman physician. He hoped the time would come when every trained nurse would be properly instructed and given a certificate which would legally constitute her an attendant on cases of obstetrics.

Dr. A. P. Dudley indorsed the suggestion regarding the training of nurses for obstetric practice.

The Trendelenburg Position in Prolapse of the Funis.—Dr. R. Abrahams read this paper. He said that it was natural that the postural treatment should be suggested, in view of the fact that the human female is the only animal in whom this accident occurred. In 1858 Dr. T. Gaillard Thomas struck the keynote of the situation in the following statements: (1) The causes of this complication are the slippery nature of the displaced part and the inclined plane offered by the uterus; and (2) the only rational treatment was to reverse these conditions by placing the woman in the knee-chest position. This position was extremely unnatural and repulsive to woman, and it could not be long endured; moreover, should rapid delivery be demanded, it was surrounded with difficulty. These disadvantages did not apply to the Trendelenburg posture, and, moreover, when the cord was once reduced it could be maintained in proper position, even though the posture be modified to make the patient more comfortable. After making the diagnosis, no time should be lost in placing the patient in the Trendelenburg position. This having been done, the carefully sterilized hand, which was preferable to the fingers, should be introduced into the vagina and kept there until after the next pain, to make sure not only that the cord was reduced but that it remained reduced. If the pains were strong and labor could be soon terminated, or the head made to engage so as to preclude the possibility of a return of the prolapse, the patient might be kept in the Trendelenburg position; but if this was not the case the patient must be lowered half way. If there was still no tendency fully to plug the os, delivery should be hastened by the use of forceps or by version. The Trendelenburg position was particularly favorable for version. In private practice a very convenient way of obtaining the Trendelenburg position was by placing the patient on an ironing-board while she was still in the recumbent position, bringing the popliteal spaces to the end of the board, and then raising the latter to the desired position, and supporting it by an inverted chair, padded with a pillow. Only three cases of prolapse of the cord treated by the Trendelenburg position had been published—two by Dr. A. Brothers and one by himself; but he had notes of six cases which had been so treated—a very respectable showing, considering that this complication of labor occurred only once in about five hundred times.

Dr. Abram Brothers said that the postural treatment of prolapse of the funis had been before the profession for many years, but it had occurred to him a few years ago that the Trendelenburg posture was better suited to this purpose than the knee-chest position advocated by Thomas. In putting the suggestion into practice he had been surprised at the ease with which the prolapse could be reduced. It seemed to him advisable to terminate delivery at the time, because of the danger of the recurrence of the prolapse from the persistence of the original etiological factors. He had then been struck by the facility with which version could be performed with the patient in this position. After bringing down one foot, it had been his rule to lower the patient to the horizontal position. After the completion of the version, when there was a tendency to a recurrence of the prolapse of the funis, he had found it desirable to insert a large sterilized sponge. When the pulsations of the cord were good there was no need for great haste in the termination of labor.

Hypnotism in Pregnancy and Labor.—Dr. Louis Lichtschein read this paper. He said that there were only three normal conditions in pregnancy in which suggestive therapeutics was useful, viz.: (1) In pernicious vomiting; (2) anorexia; and (3) abnormal cravings for particular foods, and especially for unpalatable substances not usually regarded as food. That the obstinate vomiting of pregnancy was sometimes amenable to psychical influences was shown by its amelioration or cessation by the mere change of surroundings. He had not had the opportunity to use hypnotism in complicated cases of labor, but when it could be used successfully it possessed a decided advantage over chloroform. Some pregnant women could not be hypnotized at all; others could be made to sleep only superficially; while others again slept deeply, but awoke as soon as the pain became severe. Still others slept very deeply and did not awaken during the pains, and on awakening afterward had no recollection of what had taken place. There was still another class, in which, although the patient was awake, she felt no pain as the labor progressed. Of forty-six cases of labor in which he had employed hypnotism, nine were failures; in eleven the patients slept superficially, fifteen slept deeply, ten had a very deep sleep with perfect amnesia, and one remained awake but felt no pain at all. A number of illustrative cases were narrated, including one in which it was asserted that the "suggestion" given two months previously had resulted in an unexpected and painless delivery before he could reach the bedside. During the deep hypnotic sleep the pain could not only be reduced, but it could be intensified, and the need for chloroform and forceps in some instances dispensed with. The conditions of the puerperium which might be favorably affected by suggestion were after-pains, lactation, peristaltic movements of the bowel, puerperal paralysis, and puerperal mania. An excessive flow of milk could often be promptly checked by suggestion.

A Memorial to Dr. Joseph O'Dwyer.—A resolution, introduced by Dr. T. J. McGillicuddy, was adopted, authorizing the appointment by the association of a committee of three to assist similar committees from the other medical societies in raising a fund to perpetuate in a suitable and enduring manner the memory of the late Dr. Joseph O'Dwyer.

Tuberculosis.—Inject into the gluteal region cinnamic-acid emulsion (five per cent.) 0.1 gm., gradually increased to 1 gm. Unless thrown deeply into the muscle the injections are painful. Keep up for months. Cinnamic acid powerfully influences tuberculosis. It is harmless given as above, and gradually brings about a cure in a proportion of instances of pulmonary tuberculosis, though it is not regarded as a specific.—Husser, *Therapeutische Monatshefte*, September, 1897.

Clinical Department.

INTESTINAL OBSTRUCTION CAUSED BY THE VERMIFORM APPENDIX ACTING AS A CONSTRICTING BAND.

By FREDERIC C. PAFFARD, M.D.,

SETON HOSPITAL, NEW YORK; LATE HOUSE SURGEON, GOUVERNEUR HOSPITAL.

The following case, occurring in the service of Dr. O. J. Ward at Gouverneur Hospital, is of some interest, as the constricting band, the vermiform appendix, was a most unusual one. Richardson (Dennis' "System of Surgery," vol. iv., page 304) reports but three cases on record of intestinal obstruction from this cause. The following is the history of the case:

I. F——, aged thirty-four years, married, born in Russia. Family history negative. Past history: He had an attack of abdominal pain, nausea, and vomiting, two years ago, which lasted for two or three days. Six weeks ago he had another similar attack, which lasted for six days. Operation was at that time advised by the family physician, but the patient refused. The general health between the attacks was good. His present illness began two days before his admission to the hospital. The patient complained of severe colicky pain in the abdomen and obstinate constipation. On the day of admission the patient began to vomit. Vomiting became more severe as the day progressed, and at 3:15 P.M. an ambulance was summoned, and the patient was removed to the hospital.

On admission the patient appeared well nourished; his face was drawn and the body surface cold. The abdomen was not distended. There was a lipoma as large as an orange in the median line, two inches below the umbilicus; it was partially adherent to the deeper structures. Abdominal tenderness was general, but was most marked in the umbilical region. No mass could be felt in the right iliac region. Pulse, 100, weak; temperature, 99° F. (rectum); respirations, 20. A high enema had no result. The vomiting continued. At first the vomited matter was clear green, but at 5 P.M. it contained flakes of a green color with a decidedly fæcal odor.

A diagnosis of intestinal obstruction was made and operation advised, but the patient refused to consent.

The next day the patient's condition changed rapidly for the worse. Temperature, 97.4 F.; pulse, not perceptible; respirations, 24. At this time the abdomen was greatly distended and there was general tympanites. The patient now desired operation, although he was informed that the prognosis was almost certainly fatal. The operation was performed at 10 A.M. A median longitudinal incision five inches long was made through the lipoma, and the peritoneal cavity was opened. A quantity of blood-stained serum escaped. The intestines were much distended, and a small amount of fibrin was observed on their peritoneal coat. The hand being introduced into the abdominal cavity, a constricting band was discovered, which was recognized as the vermiform appendix, stretched across the lower part of the umbilical region, and attached by its extremity to a loop of small intestine. The appendix was divided at its distal extremity between heavy catgut ligatures. The constricted gut was evidently the ileum, and was much congested. The abdomen was now thoroughly irrigated with decinormal saline solution, about one quart being left in the abdomen. The abdominal incision was then closed in the usual manner, and the patient was returned to the ward in a condition of extreme shock. Before the operation, and during the time the patient was in the operating-room, decinormal saline solution was injected into the subcutaneous tissues. After the operation large amounts of gas were expelled per rectum.

The patient died on the third day after the operation. An adhesive appendicitis had evidently occurred at the times of the attacks of "abdominal pain" previously spoken of. Had the operation for the relief of the obstruction been performed before the occurrence of general peritonitis, the prognosis might have been changed, as the patient's subjective symptoms were markedly relieved by the operation and the cause of the obstruction was removed.

The writer wishes to express his appreciation of the assistance of Dr. Charles E. Nammack.

A CASE OF LARGE UTERINE FIBROID WITH UNUSUAL COMPLICATIONS.

By CARL F. GISSLER, M.D.,

BROOKLYN, N. Y.

On May 10, 1897, Mrs. S——, aged fifty-three years, called on me for relief of a supposed uterine prolapse. On examination I found a large, solid, organized mass filling the vagina and protruding some two inches. Her menstruation had ceased seven or eight years ago. As the protruding mass was certainly not the uterus, a four-pronged volsellum forceps was applied with some traction downward with the left hand, and a beam of light was thrown upward from a parabolic gas-light reflector. A pedicle, six inches long by three inches thick, was seen attached to one side of the cervix.

On May 13th, a number of medical confrères being present, the parts were rendered aseptic, and the woman was chloroformed and a volsellum applied. At this time a dark red tubercle, a urethral caruncle, was noticed and snipped off with scissors. A female metallic catheter was applied, but, as it would not easily enter more than one-fourth of an inch, was laid aside. Then with curved long scissors and occasionally with the knife, the thick pedicle of the fibroid was severed. Very little hemorrhage followed this procedure, high up and in the dark under the guidance of the left hand. Some retractors were then put in and the stump was brought to view. It extended up into the uterus some two and one half inches, and its whitish-looking cut fibres were then again submitted to excision without much bleeding. A wick of gauze was left in the uterus after a thorough irrigation, and gauze was tightly packed in the vagina and the woman put to bed.

Two days later the gauze was removed, and this was followed by another hot irrigation and repacking with gauze.

From the fourth day on no more packing was done, but only hot injections were ordered three times a day. There was never any rise of temperature, and complete recovery followed as regards the fibroid tumor, and there has been no recurrence up to date, February, 1898.

The special interest in connection with this case was, however, an old vesico-vaginal fistula. As mentioned already, a metal catheter was tried and would not enter on slight pressure. On the day following the operation the urine was voided involuntarily in bed. A thought flashed through my mind: Did I injure her bladder? The catheter was again tried and a little more force applied, but it did not enter; neither did a fine metallic sound for more than one-fourth of an inch. The tissue in this short space on closer inspection looked extremely pale, more so than in an ordinary female urethra. It was degenerated from non-use. Immediately behind the symphysis pubis and

overlapped by an anterior transverse vaginal fold, I found a pinkish-looking orifice admitting a one-sixteenth-inch catheter into the bladder. After the fifth day the patient could voluntarily void urine. The fistulous opening seemed to functionate sphincter-like, or, what is more physiologically correct, the small, transverse, anteriorly placed, overlapping vaginal fold acted as a sort of valve under the will of the patient. At the time of the operation we were informed that a similar tumor was operated upon by two physicians, Drs. Spigler and Hergot, at Gibweiler, upper Elsace, ten years ago, and at that operation the bladder was accidentally injured in the anterior fornix of the vagina. It took some years perhaps for the insidious growth of the second cervical fibroid to develop. The existing fistula allowed the urine to pass by the fibroid, and the normal urethra atrophied into an impervious band. It was demonstrated during the week following the operation to some of the physicians who were present at that time. I think this case is of no small importance in a medico-legal light.

23 Kossuth Place.

REPORT OF A CASE OF GONORRHŒAL RHEUMATISM TREATED WITH INJECTIONS OF BICHLORIDE OF MERCURY.

By WILLIAM H. MARCY, M.D.,

BUFFALO, N. Y.,

SURGEON, WEST SHORE RAILROAD, AND RAILROAD MEN'S HOSPITAL, NEW YORK CENTRAL RAILROAD, ETC.

As a result of blennorrhœal urethritis, commonly and less frequently of a blennorrhœal ophthalmia or vulvitis, certain affections are observed to occur, which, when existing in the joints, bursæ, sheaths of the tendons, the eye, muscles, nerves, and fibrous tissues, are designated as blennorrhœal rheumatism. It is believed to be an infectious process, a wound infection, in which the follicular ulcers (gonorrhœal ulcers) in the posterior urethra are for the most part the point of infection. Taking such a position leads up to a belief in existing gonohæmia or pyohæmia, but, accepting such a belief, we must make it subject to three indications of the proof of any micro-organic origin of the disease: first, that one and the same form of micro-organism be always found in a given disease; second, that it be easily recognized morphologically by chemical relations and reaction to coloring-matter; third, that the disease be artificially reproduced in a healthy individual by inoculation with pure culture. Neisser, Bockhart, and others have carried out these conditions in so far as the urethral inflammation is concerned, but in the complication of a gonorrhœa we lack positive proof of the third condition. Very early in the history of the gonococcus as the cause of a specific urethritis, the conclusion was that this micro-organism must be held as the direct cause of its complications. Ehrlich and Haslund, after a careful study of the subject, denied the presence of the gonococcus in the joint effusions following gonorrhœa of the urethra or vagina. Kammerer, Hale, and others have found a diplococcus in the joint effusions, resembling somewhat the gonococcus, but not producing the necessary proof obtained from cultures. Many theories have been presented, but none thoroughly proven; but we must consider gonorrhœal rheumatism as an infectious arthritis due to a micro-organism, from which distinct pathological conditions of the following nature may arise: serous, sero-fibrous, sero-purulent, and purulent. The outcome of these may be either a complete resolution or an ankylosis of the joint involved. Statistics show that in 35 per cent. of cases there is recovery; in 65 per cent. motion is restricted or completely lost. The frequency with which the various joints are involved is, according to Nolen: knee, 43 per cent.; shoulder, 25 per cent.; hip, hand, and fingers, remaining 32 per cent. In the majority of cases it occurs during the first month, but may not occur until the second or third month.

After these introductory remarks, I wish to present the history and treatment of a case of gonorrhœal arthritis recently under my care.

Mr. C——, aged thirty-two, contracted gonorrhœa March 3d. He was treated by his family physician for three weeks. The urethral discharge at the end of this time was slight and of a milky character. He was suddenly taken with severe pain in the left knee, followed by swelling and fever. Applications were made to the knee, and internally he received colchicum-salicylate capsules every two hours; cathartics and alkaline waters were freely given. He gradually grew worse for fifteen days, the salicylates having no curative action. With the idea that he would receive better nursing, he was taken to the General Hospital for treatment. The salicylates were continued, and blue ointment was applied to the painful knee. The diet was principally milk with alkaline waters. No improvement took place. The knee was intensely swollen, the temperature remaining high. I was called to take charge of the case. The same diet was continued; the bowels were kept active with Carlsbad salts, and water was given freely. The iodides were tried, but nothing but morphine would quiet the pain, and quinine had only slight control of the fever. The temperature reached every night about 104° F., with excruciating pain. Something had to be done. Appreciating his trouble as a toxæmia, and having aborted a few cases of tonsillitis (which under other treatment had always terminated in suppuration) by the injection of bichloride-of-mercury (1 to 3,000) solution, I decided to institute the following treatment. The knee at this time was intensely swollen but contained no pus. I selected a hypodermic syringe of sixty minims capacity, tipped with a needle of sufficient strength and about one and one-half inches long. The syringe was partly filled with a four-per-cent. solution of cocaine. The knee was rendered aseptic. The skin was anæsthetized with a few drops of cocaine, and as the needle was inserted the parts were cocainized until the needle was introduced its full length without pain. I drew the piston, but found only a small quantity of fluid of a yellowish nature within the joint. The syringe was unscrewed from the needle, the latter being left still inserted. The syringe was then filled with sixty minims of 1 to 3,000 solution of bichloride of mercury, was reattached to the needle, and the solution injected. The needle was withdrawn and the point of insertion sealed with collodion. The results were as follows: The temperature, which had stood for weeks around 103° and 104° F., dropped to 99° F.; the pain that morphine would not quiet became easier. This treatment was kept up for three days, night and morning, with a temperature at about 99° F., when the injection was discontinued for two days, during which time the patient became worse, the temperature reaching 103° F. I began injections again, with the same marked improvement, and the patient made a rapid recovery. No stiffness followed and the patient to-day is as well as ever.

From a study of this case we may draw the following conclusions: that gonorrhœal rheumatism is surely an infectious disease, due to metastasis of micro-organisms to the joint involved; that it is a local trouble; that the toxæmia is due to the absorption of ptomains; and that if we can reach these micro-organisms direct and not use the circulation as a vehicle, the more brilliant will be our results.

OUR LONDON LETTER.

(From our Special Correspondent.)

DIPHTHERIA ANTITOXIN, REPORT OF THE CLINICAL SOCIETY'S COMMITTEE—SCOTCH MEDICAL OFFICERS OF HEALTH—THE "LANCET'S" SHORT STORY—THE ASYLUMS BOARD—LIFE OF STOKES—GORDON'S REMINISCENCES—SURGICAL TEXT-BOOKS—THREE ENTERTAINMENTS.

London, June 10, 1898.

The report of the committee on diphtheria antitoxin was presented to the Clinical Society at the annual meeting held on the 27th ult. This committee was appointed in 1895, and determined to conduct the inquiry as follows: 1. To test the effect of antitoxin on the mortality of diphtheria. 2. To analyze the evidence obtained as to the effects of antitoxin in proportion to the quantity administered: (*a*) on the course of acute disease; (*b*) on the complications and sequelæ. 3. To note any other effects of antitoxin.

The co-operation of hospitals was invited and eight hundred and thirty-two cases were analyzed and tabulated by a subcommittee. Out of these collected reports one hundred and ninety-nine cases had to be rejected from defects of evidence or imperfect statements, leaving six hundred and thirty-three for further analysis. The cases were grouped according to the seat of the membrane and the effects of the remedy noted as to mortality, extension of membrane to the larynx, paralysis, symptoms caused by the antitoxin, and conditions under which death occurred.

The general result of this important inquiry shows that in cases treated with antitoxin not only is the mortality notably lessened, but that in fatal cases life is prolonged. The injections may produce rashes, joint pains, and fever, but no other prejudicial effect after even very large doses. In support of this conclusion I add a few particulars as to the points investigated. As to mortality the cases were arranged in two series: one in which the whole of the antitoxin administered was injected within the first forty-eight hours of treatment; the other in which it was continued longer.

Of the laryngeal cases one-half escaped tracheotomy—a much larger proportion than under any other known treatment. Of the tracheotomies performed, only two were done after twenty-four hours from the first injection. Further, the mortality of the tracheotomies was only thirty-six per cent., which compares very favorably with a series of records from the general hospitals before the introduction of antitoxin and which amounted to 71.6. The effect of age seems much the same as under other treatment. The lessened mortality appears to depend on the lesser frequency with which the membrane extends to the larynx under the influence of antitoxin. The total mortality of the 633 cases amounted to 124=19.5 per cent., as against 29.6 in the hospital series before antitoxin.

The duration of life in fatal cases was prolonged, a fact to which the committee draws attention in reference to the occurrence of paralysis. As to this, the closest investigation failed to show any connection between the occurrence of paralysis and the amount of antitoxin injected, or the period of the disease when it was used. Rashes were observed in about one-third of the cases, chiefly erythematous or urticarial, but in no instance had they any bearing on the ultimate result. Joint pains were noticed in a few cases, nearly all of which had a rash and some fever. In some cases a rise of temperature occurred during convalescence, without either rash or joint pains. Suppression of urine was in the same percentage with and without antitoxin.

The report states that a very large proportion of the cases have been personally observed by members of the committee. We may therefore feel assured that it will receive the attention of all interested in the subject. On the motion of the president, the society unanimously passed a vote of thanks to the committee for its valuable services. The report of the council for the past year was then read, showing a membership of five hundred and eighty-eight and a satisfactory state of the finances. A general index to the first thirty volume of the society's Transactions has been issued.

The Association of Scottish Medical Officers of Health is issuing a memorandum on its duties and sphere of action under the new Scottish public-health act. The memorandum seems to be conceived in a reasonable spirit, and is likely to prevent friction between the M. O. H. and other medical men; it shows that the M. O. H. should start with the belief that practitioners' certificates are given in good faith, and it is no part of the officer's duty to review the attendant's diagnosis. A number of other points are considered in the memorandum, all of them in a similar strain, and its circulation is calculated to raise the society in professional estimation.

The Lancet has come out with a short story. The bald statement of the fact looks almost startling now it is on the paper, so explanation may be desirable. You know the great interest of your contemporary in the hospital Sunday fund and how for several years it has issued a special supplement for distribution in the places of worship on hospital Sunday. Well, that day is upon us again. *The Lancet's* twelfth supplement was issued last Saturday, to be ready for next Sunday, and this supplement, consisting of an earnest, well-reasoned appeal, supported by full statistics, winds up with the short story in question. It is intended to show how an annoying accident would be transformed into a tragedy if there were no hospitals. It is not easy to imagine the condition, but the simple story may catch some who shun the columns of statistics.

The extravagances and mistakes of the Metropolitan Asylums board have often excited comment and even indignant remonstrance. Even the local government board is expressing dissatisfaction and demanding information. When public indifference is once overcome, reform will be insisted on and the blame of the past awarded. The Brook Hospital expenditure is now said to exceed the architect's estimate by £70,000. The amounts that have been squandered on the hospitals of the asylums board constitute a scandal. Unless thorough investigation is made and some check to extravagance given, the government may have to reckon with widespread discontent.

The life of Dr. Stokes, by his son, has appeared in the "Masters of Medicine" series and gives an intensely interesting account of the great Dublin physician, his life and work. Any doctor who knows nothing about Stokes is very imperfectly educated.

Sir Charles Gordon's "Reminiscences" cannot fail to interest a large number of civilians as well as army surgeons, for he served in many countries from his assistant surgeoncy to the principal medical officership of Madras, and carried into all these countries an observant, scientific mind. His journey to Burmah with the Duke of Buckingham was the subject of a former volume.

Two new surgical text-books are issued here—"A Manual for Students and Practitioners," by W. Rose and A. Carless, both of King's College, and "Outlines of Practical Surgery," by W. Spencer, of the Westminster Hospital.

The Royal Society gave a *conversazione* on Wednesday which was quite a fashionable crush. It had been anticipated that Professor Ramsay would give a demonstration of the spectrum of the new element he has discovered in the atmosphere, and which he calls krypton, to signify that it has up to now been concealed. Would it not be more natural to give it a name signifying that at length it has been revealed? Of course you have heard of the discovery, and some of its characteristics have been described. It gives two brilliant lines in the spectrum; is a gaseous, non-atomic element, and estimated as present not above one in ten thousand volumes. The other scientific exhibits were numerous and extremely interesting.

The metropolitan branch of the British Medical Association gave a *conversazione* on Tuesday in the museum of the Royal College of Surgeons, at which some two thousand guests were present. The attractions of the great collections in the museum were reinforced by the band of the royal artillery, and the lecture theatre was given up to solos, quartettes, and humorous sketches.

Another *conversazione* was given on Wednesday by the Balneological and Climatological Association, when Dr. Poore gave an address on circumstances which influence climatic treatment, and Dr. Hedley showed a new form of stereoscope for exhibiting *x*-ray pictures in relief.

Three such entertainments in one week should be enough.

OUR PARIS LETTER.

(From our Special Correspondent.)

INFLUENCE OF THE SPANISH WAR ON THE PRACTICE OF MEDICINE, PHARMACY, ETC.—ALSO FELT AMONG ELECTRICIANS AND HYDROPATHS—FRENCH MEDICAL AND INSURANCE SOCIETIES, UTILITY OF—PROFESSOR PANAS AND DR. SCRINI SUBSTITUTE OLEAGINOUS FOR AQUEOUS COLLYRIA IN THE TREATMENT OF DISEASES OF THE EYE.

Paris, June 11, 1898.

The war between the United States and Spain has begun to make itself felt here in a professional way. Several of the leading American physicians in Paris have hitherto had a clientèle composed largely of their compatriots; there is now, however, considerable falling off in the number of those coming from America. People not knowing yet how long the war is going to last or how it is going to affect their incomes, remain at home. There is a correspondingly marked falling off in practices. The French consulting physicians and professors of the faculty are also beginning to feel it; whereas they were called in consultation almost every day or two before the war, consultations now with American physicians are becoming exceptional. The chemists and druggists, on their side, are complaining too that business is rather slack, the prescription department is not so active as it was this time last year, and the opportunities for giving professional advice as well as medicines at the counter are less frequent. Not that the Americans have "boycotted" French doctors or pharmacies, as the ladies have "boycotted" French millineries on account of Spanish sympathy, but simply because there is less travel to Paris and there are fewer visitors here than usual, on account of the Hispano-American conflict. Not only do fewer come here from the United States, but many of those returning home from different parts of Europe prefer to pass Paris by and sail from England, Germany, or Italy.

Electricians, hydropaths, and masseurs also come in for their share of the diminution in clientèle and deficit.

The combination of insurance with medical societies, by which they become, as the French say, a "work of aid," obtains perhaps to a greater extent in France than in other countries, and is another evidence of the thrift and wealth of the French people. It is a custom that might with advantage be imitated to a larger extent than it actually is in America. One of the more important of these in Paris is the "Mutual Medical Association of the Department of the Seine." By paying a tax of ten francs a month, any doctor of medicine practising in the department of the Seine may acquire the right to an indemnity of ten francs ($2) for every day of professional incapacity, either temporary or permanent, caused by illness or accident, no matter how long the duration. The aged, the infirm, and those entirely incapable of practising receive the same indemnity as in case of illness. In case of the death of a member of this medical insurance society, his widow or children are allowed an indemnity proportional to the importance of the reserve capital of the organization. Others of these societies are the Syndical Association of Foresight and Mutual Aid to French Physicians, of which Dr. Lannelongue is the president; and the Amical Association of French Physicians, whose objects and system of management are similar to those of the first named. These three have what is called their "siège social" in Paris, but similar societies exist in all the principal cities of France.

Dr. Panas, the eminent professor of diseases of the eye, proposes to employ in his clinic at the Hôtel Dieu collyria of oleaginous solution instead of the aqueous solutions he has hitherto used. Professor Panas has found that after a certain time aqueous collyria become cloudy and precipitate cryptogamic productions. Moreover, in order to instil usefully these collyria into the eye by means of a dropper, it is necessary to open wide the lids, which it is difficult to do when there is photophobia with blepharospasm, especially in children.

Oily solutions possess the advantage of remaining aseptic when they are well prepared and are not irritating to the external membranes of the eye, as demonstrated by the work of Dr. Scrini, the pupil of Professor Panas. The most interesting collyria from a practical every-day standpoint are those of atropine, eserine, pilocarpine, and cocaine. As the salts of these alkaloids are only slightly soluble in oil, recourse is had to the bases, which are soluble, and of which solutions are made of one per cent. for atropine and eserine; of one to two hundred per cent. for pilocarpine; and of two per cent. for cocaine. Olive oil should be preferred in making them, first freed from fatty acids by washing in alcohol at 90° F., then sterilized by heat at 120° F. It is subsequently allowed to cool to 60° F., and the organic base is added, which dissolves therein completely. The collyria prepared in this way retain their transparency and sterility a very long time, during which they undergo no chemical decomposition, nor do they produce any alteration upon the epithelium of the cornea or conjunctiva. They should be applied on the extremity of a small glass blunted spatula, dipped in the liquid and passed along the palpebral slit slightly opened.

THE BUCCAL ERUPTION OF MEASLES.

To the Editor of the Medical Record.

Sir: In reading my Medical Record of June 11th I came across the article by E. Libman, M.D., "The Value of the Buccal Eruption of Measles for Early Diagnosis," in which he gives the credit of the discovery to Dr. Koplik, of New York City. In February or early March, 1881, my attention was called to the buccal eruption as a diagnostic sign of measles by a

lady in Carroll County, Ind., and I have verified the truth of it in a number of epidemics since then. In fact, it had become a habit with us country physicians to inspect the buccal mucous membrane for the signs of measles years before Dr. Koplik ever published a word on the subject. GEORGE R. CLAYTON, M.D.

MONON, IND.

THE DIFFERENT FIELDS OF OPERATIVE SURGERY AND GYNÆCOLOGY IN EUROPE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Buda Pest is one hundred and seventy-three miles southeast of Vienna, and from the former place I went five hundred and seventy miles northwest to Munich, a city of nearly four hundred thousand inhabitants. The altitude is seventeen hundred feet, the sky pleasingly clear, and the air pure. The national beverage of Germany is made here in its greatest perfection, if not greatest quantity, and he who will call often enough for his "Münchener," and pronounce it correctly, will pass current anywhere in Germany, especially in Berlin.

Munich is the capital of Bavaria, and of course the language of the place is German. The university here, I am assured by one of its professors, has a larger number of matriculants in the summer term than that of Berlin. The hospitals are large and the clinical material is abundant.

Winckel, whose work is a recognized text-book in many medical schools of America, is professor and director of the Frauenklinik, where he operates daily, except on Sunday and Saturday, from 8 to 10 A.M., and lectures from 10 to 11 A.M., and from 11 A.M. to 12:30 P.M. On each day six students, whose names were called the day before, come into the arena, each having a cot with a patient, and in succession give the history, make the diagnosis, and prescribe treatment, all in answer to the professor's interrogations, for the benefit of all present in the amphitheatre. Winckel refuses to take any one into his class for less than six months.

Since July, 1897, he has operated after Mackenrodt in all cases of carcinoma of the genitalia, discarding the knife entirely. Winckel is probably more than sixty years old; he is short and stout; has a full beard closely cropped, and brown hair; and is most serious in all his acts and language, never suggesting levity or a smile.

Angerer is perhaps twenty years younger than Winckel. He is strikingly tall, has glossy black hair and beard, black eyes, and is most suave of manner. He is professor of surgery and director of the same clinic in the hospital. He is a speedy and fearless operator and has abundant material. Besides the university hospital, supported by the government of Bavaria, there is an addition adjoining (though this is entirely supported by the city) that has communicating halls; and all is under the direction of Angerer. There is a total of three hundred and twenty beds, in which were thirty-nine hundred and ninety patients in 1896. In the same year there were nearly six thousand ambulant patients. There are fifty nurses, mostly "sisters." This title is given only to such as are Catholics and members of a religious order which gives them a distinct title and garb. They attend operations in the amphitheatre, handing instruments and surgical accessories; they perform the same services in operations on the genitals of males as in other cases. In hernia cases Angerer cuts after Bassini exclusively. Subcutaneously he uses catgut and interrupted sutures, while for outer stitching he uses silk and continuous suture. He is one of the very few continental surgeons who prefer ether to chloroform. Angerer was appointed to his present position seven years ago. He is a man of fine presence, affable, gentle to patients, and considerate to assistants—the latter a rare characteristic in a German professor. I find him the most genial German of that title thus far seen in any clinic.

In the land of Baden, and almost due north from Munich, two hundred and twenty-two miles, is the celebrated city of Heidelberg, with its historic castle and well-known university. The city is built on a long and narrow bluff of the Neckar, and forms the key to the mountainous valley of that stream where it opens into the plain of the Rhine. The city has only thirty-five thousand people, but the university and its hospitals, supported by the government of Baden, are ample in size and material for educational purposes. The hospital for Frauenkrankheiten has obstetrics and gynæcology within the same building, over all of which Professor Kehrer has been director since the completion of the hospital in 1886. He is an elderly gentleman, and an instructive teacher and operator. There are separate rooms for laparotomy and vaginal operations. There are twenty-five beds in the gynæcological department, in which six hundred and three patients were treated in 1897. In the same year there were nine hundred ambulant patients. All the latter and obstetrical patients are treated without pay. There were four hundred and twenty-one births in the hospital in 1897. There are no free gynæcological beds in this hospital. Patients of the first class usually have a room for each and pay 7½ marks a day; those of the second class pay 5½ marks a day, and are placed not more than four in a room; those of the third class pay 2 marks a day.

There are two resident assistants and one volunteer. The latter pays 40 marks a month, which secures him residence within the hospital and everything furnished, including board and washing. Professor Kehrer is furnished residence and living in a separate building on the hospital grounds, a few hundred yards from the hospital, with telephone connection, so that he may be called promptly when needed.

In closing the incision of cœliotomy Kehrer sews the peritoneum first with continuous catgut, while the inner surfaces of this membrane are held up and pressed together along the cut edges, and second, with silver or silk interrupted sutures. He sews with the novel method of having a needle at each end of the suture and working from within outward. He passes first through the fascia one needle on each side; then, crossing the suture like an X, he penetrates fat and comes out through the skin, about half an inch from the cut edge. Whether he has silk and ties or silver and twists, neither fastening is made over the incision, but carefully on one side, where the suture emerges and still outward from the puncture. When wire is used, the twisted ends are further turned away from the incision over a soft pad on the outer side and away from the wound. Kehrer places stress on the importance of not operating on a woman for from three to five days after she enters the hospital, that she may become accustomed to her surroundings. Two days before operating he gives her a general bath and repeats this the next day, and on the morning of operation, if vaginal, a sitz bath is given; if a laparotomy, the line of proposed incision is shaven and scrubbed with a brush, first, in soap and water; second, in alcohol; third, in sublimate, 1–1000. For those concerned in the operation the same precautions as to the hands are observed, except that the first step is longer continued; in addition the principal and all assistants must rinse the teeth, mouth, and throat thoroughly with cognac. On seeing Professor Kehrer spit this out I assured him that in my country very little cognac is spit out of the mouth. He asked me, excitedly, to watch his first assistant, who expectorated no cognac, though he rinsed with the painstaking method of his

chief. The professor thinks it very important to disinfect the mouth immediately before laparotomies, and believes cognac to be the best disinfectant for this purpose.

The originator of the Czerny suture is professor of surgery in the University of Heidelberg and director of the hospital of the same designated branch; he does considerable gynæcological work but no obstetrics. About two-fifths of his patients in the hospital are females.

I was interested in seeing this eminent surgeon and accomplished diagnostician in doubt as to the diagnosis of a decidedly enlarged liver. The patient was a man of fine, delicate features, and by occupation a "Künstler," aged forty years. Between hydatids and cirrhosis Czerny inclined to the belief that it must be the latter, assuring me that in the twenty-one years he had served in his present position he had not seen a case of echinococcus in Baden. He finally decided to operate, and made an incision about three and one-half inches long, close to the inferior border and parallel with the lower rib. When he got his fingers between the lobes of the liver he found fluctuation and did paracentesis, by which he got twelve centigrams of clear fluid containing echinococci, revealed only by the microscope. Czerny retained his belief of freedom from this form of entozoa in the country of Baden, as his patient was an artist who had lived in Italy, Paris, and Copenhagen. In Austria and Hungary this is a common disease.

Czerny has large grounds, over which are scattered seven pavilions, surrounded with trees and ample lawns. There are in these pavilions two hundred beds, in which twenty-five hundred patients are treated yearly; also seven thousand ambulant patients, making a total of fifty-five thousand days annually. In 1897 Czerny did two hundred and twenty laparotomies, not counting hernia operations.

In the operating-room there is ideal light. About half of the amphitheatre roof is skylight and at the side of the arena there is a window, about twelve by twenty feet, overlooking the Neckar from a high bluff, where it will be free forever from obstruction of house or tree.

Czerny has three resident and three volunteer assistants. The latter pay 40 marks a month each for living in the hospital, having everything furnished them. They assist daily at operations, the same as other assistants. There are twenty-five sisters, who are skilled nurses, and seven in training in the surgical department. Czerny is perhaps sixty years old. He has the stature, beard, chin, eyes, and features generally of ex-President Harrison, his nose being a cross between that of Harrison and that of the late Roscoe Conkling. To such as believe men can become great only in great cities, Czerny is sufficient answer. Among the German-speaking people no surgeon is more widely known or more esteemed by other surgeons. Only a short while before I was at Heidelberg he had been in Constantinople as consultant in the family of a pasha. When I asked Czerny if he thought Heidelberg a large enough city for a surgeon whose name is equal to the greatest in Germany, he answered jocularly, "We care more here for a great name than for a great city," and left me guessing as to whether he was alluding to Czerny or to Heidelberg.

Slightly south of west and four hundred and ten miles from Heidelberg is the metropolis of continental Europe, the luxuriant city of Paris, with its two and one-half million inhabitants, who are so entirely French in their railroad stations, post-offices, street conveyances, and restaurants that it is impossible for one who cannot speak their language to make himself understood. With a slight knowledge of this language one learns it much more rapidly than he learns the German when living among its people.

Paris is a city of hospitals, it having twenty supported by the public, with an aggregate of twelve thousand beds, from which are discharged annually about one hundred and ten thousand patients, of whom forty thousand are women. The annual average of deaths in these hospitals is seven thousand men, five thousand women, and three thousand children. The Assistance Publique expends annually 36,000,000 francs on benevolent institutions, which assist about four hundred and sixty-seven thousand persons.

Hospitals here are not conducted with the same regard for specialism as in other parts of the continent. Insane, incurables, and invalids of all sorts enter into the sums total of beds of almost every hospital. In the hospital where I had expected to see gynæcology practised more exclusively than in any other public clinic of Europe, an amputation of the upper third of the humerus for sarcoma was the first operation I witnessed, and the last was the removal of the superior maxillary for carcinoma—the latter patient a male.

The clinic of Pozzi I visited shortly after my arrival. This accomplished author is tall, has black hair and eyes, closely cropped beard, intellectual face, and is in middle life. He has a large class of students and nurses, male and female. Instead of the Paquelin he uses a heated iron in vaginal operations, and even intra-uterine.

One of the brilliant operators of Paris is Doyen, who is regarded as a general surgeon, although about half his work appears to be gynæcological. He resides an hour or two away from Paris, and is irregular as to days, hours, and places of operations. One needs to be long in Paris to see much of this father of methods and instruments, many of which bear his name.

Richelot is ostensibly a gynæcologist, but, like other Parisian operators, he appears to cover the general domain of surgery. He has unlimited material at the large hospital of St. Louis. While he does not pose for much rationalism or so-called brilliancy, he is a conscientious worker and a prudent observer, with a marvellous memory of the mistakes and follies of men in his line. He has doubtless had forty years' experience in surgery, and I find his clinic well attended by Americans. Before entering upon intrapelvic operations per vaginam he washes this channel with a brush having bristles on both sides and a long stout handle, using soap and warm water. The uterine canal is cleansed with glycerin and creosote, thirty per cent. of the latter. He does hysterectomy by colpotomy and by cœliotomy in about equal proportions.

The most likable companionship I formed while abroad, that with Segond, was the most intimate and lasting. I gave him gladly four-fifths of my entire time in the hospitals of Paris, and saw him operate when blood flowed and spurted, but never saw him irritable or severe in any remark made to an assistant or attendant. A child playing in sand manifests no greater happiness than does Segond while operating, though I have seen him do five major operations in three hospitals within a day. When a clamp slipped off the uterine artery and blood came with the rush and noise of a hydrant while he was doing a vaginal hysterectomy, he placed his thumb on the iliac artery within the pelvis, turned with a smile, and exclaimed "All right!" with the cuteness which a Frenchman's English alone can express, reapplied the clamps, and completed the operation without the loss of much time; and the patient got along as well as if nothing had happened.

Like his old master, and for long his colleague and friend, the late Péan, Segond is loath to do a laparotomy, preferring when possible the vaginal route. He is a typical Frenchman, and with the French instinct reverences the symmetry and beauty of the pristine

female form, and hesitates to mar it with even a visible scar. When he is compelled to do a cœliotomy he stitches through all the abdominal tissues, to avoid making much of a scar. For this his only suture is silver, which, like Kehrer, he twists carefully down one side, over and outward from the emergence of the suture, which is further bent outward over a pad.

When his colpotomy is for oöphorectomy he does not care to save the uterus. He says, "A uterus without ovaries is like a gun without powder." Conversely, when the hysterectomy is by the lower channel he is conservative as to ovaries, believing with Polk and Pryor, of New York, that the danger of sepsis from the ovary is infinitely lessened, whether left in part or in entirety, by reason of the natural drainage. He also values the chances of retaining plump breasts, round limbs, and general female attractiveness.

Segond never uses sutures in doing vaginal hysterectomy; he always uses clamps. He packs the pelvis with sterilized gauze, which is done up like a roller bandage and charged with iodoform powder for a distance of perhaps two feet from one end, which portion he packs carefully against cut surfaces, the rest being used to fill any vacant space and to wrap around the steel instruments, to prevent sloughing of mucous membrane.

For a multiform fibroid or a very large fibromyoma Segond will do a cœliotomy, and in the former type he will break adhesions of the smaller projections with his hands, and then, with an instrument of his own invention, resembling a corkscrew of colossal size, fastened deeply into the centre of the tumor, he pulls this out of the abdominal cavity and completes the removal with marvellous rapidity, seldom requiring more than fifteen minutes. I have seen him throw away such a growth in ten minutes after his knife had first divided the skin of the abdomen. Myoma requires perhaps twice the length of time, but by his method of peeling adhesions away from the tumor with the finger nails—the nail side of the thumb and fingers against the tumor—and clamping off vessels until after the neoplasm is removed, the operation is quickly done compared with the usual method of ligating, etc. Like Doyen, he believes the shock incident to the removal of whatever the surgeon goes after is better borne in the early part of the operation, and it ought therefore to be accomplished as quickly as possible, leaving the ligating of vessels, clipping, coapting, and sewing as the finishing part of intra-abdominal operations.

Perhaps no other operator removes per vaginam more fibroids or any of larger size, and here Segond has the same kind of a corkscrew but of smaller size, and with it a double-edged knife curved on the flat. This knife has a long handle, but the blade, sharp-pointed, is precisely the same in length as the spiral part of the corkscrew, thus enabling the surgeon always to know that his knife is not deeper than the corkscrew, the latter pulling the growth so tensely that the danger of going beyond the neoplasm is almost *nil*. Morcellations are thus done deftly and quickly, often in less than half the usual time of other methods. I witnessed removals of mixed tumors. In one case the inner portion was of the color and consistence of soft veal, while the outer shell, of about two and one-half or three inches, was more like cartilage. For myomectomy or morcellation I have seen nothing so practical as Segond's corkscrew. In vaginal hysterectomy and colpotomy for any purpose, Segond is easily the cleverest operator I have seen in any country.

In Paris all surgeons whom I saw wore long finger-nails, some having them cut to a long sharp point, but in preparing for operations great pains are taken in cleansing and purifying with chemicals. Richelot and Segond have the same process, viz.: First, scrubbing with brush in soap and warm water; second, washing in pure alcohol; third, in permanganate of potassium, 1 to 100; fourth, in bisulphate of sodium, saturated solution; fifth, in sublimate, 1 to 2,000.

Nearly two hundred miles northeast of Paris is the interesting city of Brussels, the capital of the most populous country of the world. The city has about six hundred thousand inhabitants, is the home of the King, and has a university with about one thousand medical students. The more cultured Belgians speak preferably French, though the masses speak Flemish.

About three miles from the centre of the city, behind and below a large church on an obscure street in the suburbs, is a two-story building of rough brick, hard against the street, the exterior being as unpretentious as is the location. It is two hundred and eighty feet long and about forty feet wide. Along its entire length at the rear there is a garden of flowers, trees, and walks of most inviting character. Inside on the second floor are spacious rooms with expensive fur rugs and luxuriantly furnished rooms, each containing one large bed, and in one corner of the room, behind a partition wall, a small lounge. On this a nurse sleeps the first three nights after operation on the occupant of the room, who is a patient of the first class, treated by the well-known gynæcologist Jacobs. He is the owner, proprietor, and operator of this hospital, which he began building when he came here in 1891, by erecting about one-third of the present structure and subsequently adding to each end as his increasing reputation and *clintèle* required. There are now forty-two beds for patients of three classes. Those of the first class, always one in a room, pay 18 to 21 marks a day; those of the second class, not exceeding four in a room, pay 5 marks a day. Both classes pay besides for operation. Those of the third class pay nothing for operation and are kept free of charge in the hospital. Jacobs receives nothing from the city for their keeping. For these there are two wards on the lower floor, one having eight, the other ten beds. He treats about four hundred patients yearly in his private hospital, averaging two hundred laparotomies and one hundred colpotomies.

The operating-room is on the upper floor, has an abundance of light, is finished with glazed tiling, cement, paint, and polish. The operating-tables are of brass, each surrounded with a brass railing, at opposite ends of the long room, one being for abdominal, the other for vaginal operations. The latter has two brass plates, shaped to fit the hips, with an open space between for débris to pass down into a large brass bucket over a sliding plate of glass. No rubber hip pad is needed here. Jacobs tells me the late Professor Lusk ordered one of each of these tables, which are manufactured in Brussels and cost from 500 to 700 francs each. Everything within the operating-room and hospital is practical and nothing incomplete; much is elegant. Jacobs is not large of stature and is strikingly young in appearance, reminding one of the brighter advanced assistants one sees often in Germany, from thirty-two to thirty-five years old. Except for a long mustache of dark sandy shade, worn after the fashion of the German Kaiser, his face is clean shaven. He is of German birth and education, but speaks French, English, and of course Flemish. Jacobs is cosmopolitan, having made repeated visits to America and done forty-three hysterectomies on our side of the water. The iron-dyed silk manufactured in Philadelphia is the only kind he uses. Before operating he cleanses the parts, the same as his hands, with a brush, using, first, green soap and warm water; second, saturated solution of biborate of sodium and carbonate of ammonium; third, alcohol; fourth, formalin, three or four per cent; fifth, ether. Like Dollinger and Segond, he burns alcohol in the trays for his

instruments and the receptacles for pus before using them. He prefers the vaginal route for hysterectomies when practicable, except for carcinoma. More than a year ago he expressed himself adversely and predicted that this will soon be an operation of the past, basing his opinion on personal experience. To me he said: "I believe, with Kelly, that removing a carcinoma of the cervix or uterus is not curative without the removal of the infiltrated adnexa, and this can be done only through the abdomen, where one can see the parts."

It is now fifteen months since he began doing laparotomy exclusively for carcinoma of the uterus, and he has forty-six cases on his record. All the patients are living and none give indication of a return of the disease. It is a year and nearly a half since he discontinued the use of clamps for vaginal hysterectomy, and he has in that time not had a case of sepsis, although he has removed forty-two fibroids per vaginam since his change in technique. In doing abdominal section he stands on the right side of the patient and cuts from above downward, placing the woman in the Trendelenburg position after reaching the peritoneum. On exposing the fundus of the uterus, he grasps the ovarian artery and ligament between the thumb and finger, severs them with scissors before applying clamp or ligature, turns the cut edge so that he can see the end of the severed artery, and then applies a small clamp accurately on the vessel. Before the clamps are removed all blood-vessels are ligated. He was less than twenty minutes in removing the uterus in the first abdominal hysterectomy I saw him do. He has only two assistants besides the one giving the anæsthetic; one helps at the operation, the other threads needles and hands instruments. Jacobs does no Alexander or ventral fixation. For retrodisplacements with adhesions he will massage two or three months if necessary. Other means failing, he will fasten the fundus to the peritoneum.

From Brussels *via* Ostend, the Channel, and Dover, it is two hundred and twenty-two miles to London. Here we have a different condition of things as to charities. The hospitals, I believe, receive no government support and comparatively little municipal, they being almost entirely supported by voluntary subscriptions, donations, and bequests. An accomplished chronicler, writing for one of the leading American medical weeklies, gives these good people credit for paying in this voluntary manner five million pounds sterling annually—more than £1 for each man, woman, and child in the capital. As this was written only about a year ago, I inquired if it could be possible, and found such an amount so contributed; but the list of institutions thus assisted includes many charities not hospitals, comprising "hospitals, dispensaries, asylums; bible, tract, missionary, and district visiting societies; provident homes, orphanages, etc." The regard for hospitals and the generosity of the Londoner are suggested in what is accomplished in one day. There is a "Hospital Sunday," on which collections are made in all the churches of the city for hospitals. This produces a yearly revenue of about £45,000. Non-churchgoers have a similar opportunity offered them on "Hospital Saturday," when about seven hundred and fifty ladies stationed at street corners receive contributions, thus realizing about £7,000, while collections made in the workshops at the same time add £13,000.

The required time of attendance at the medical schools before the student is eligible for examination for his degree is five years, and each school appears to have a large hospital for its exclusive use. This I found true at St. Bartholomew's, St. Thomas', Guy's, the London, and King's College. St. Thomas has the finest structure of all the London hospitals. It is beautifully situated on the bank of the Thames, directly opposite Westminster Palace. It has two hundred and fifty beds, from which are discharged yearly from six thousand to seven thousand patients. Professor Cullingworth has the gynæcological department, with twenty-one beds, all in one ward, in which are treated about two hundred and fifty patients annually. Sixty laparotomies were done last year. Vaginal hysterectomy is done only for carcinoma. This he, like all operators in London, does with the knife, believing the Paquelin has not come to stay. Pus he evacuates mostly through the belly, when at all, but he is slow in cutting for this. Cullingworth does ventral fixation by including the fascia with the peritoneum, using catgut.

In London I noticed greater liberty taken with the endometrium than at clinics in other cities, in the use of sounds, caustics, etc. A favorite application after curettage is Churchill's tincture, but often a stronger preparation of iodine is used—iodine and equal parts by weight of potassium iodide, spirit, and water.

Cullingworth has lately been making experiments with douches of simple warm water after curettage, having his chief nurse especially observe the comparative amount of discharge, and she has uniformly reported less when the simple douche was used. During the first clinical hour he made six examinations and used the uterine sound in five, by which he carefully noted the length and direction of the uterine canal, these being his chief reasons for using this erstwhile popular instrument. He uses Robert Barnes' old wooden table, which admits of no Trendelenburg position; but a new operating-room is being built with a Trendelenburg table.

At Guy's Hospital there are about six hundred students. There are no obstetrical beds, but there is an out-patient department which delivers about three thousand children yearly. Six undergraduates reside within the hospital to attend to this work. They may call regular internes to assist in difficult cases, and internes may in turn call their chiefs when necessary. There are nineteen gynæcological beds, which will be increased to forty in the new building now nearly completed. Drs. Galabin and Horrocks are chiefs of this department and come twice a week to operate, one beginning at 2 P.M., the other following at about 3 P.M. The operating-rooms, like the wards, are heated by open fireplaces, which are prolific of more smoke than heat. The floor is of wide boards, soft wood, and there is considerable furniture in the operating-room, pictures, etc., on the wall. Galabin does not remove fibroids unless the tumor is very large and the woman very young, because after the menopause the tumor will diminish and soon cease to be serious, and for this reason he will establish premature menopause by oöphorectomy and leave the tumor alone. His colleague takes the opposite view, preferring to remove the neoplasm and leave the ovaries in the pelvis, that the breasts may remain plump, the limbs round, the abdomen not take on fat, and the face not lose its feminine charm.

At the Samaritan Free Hospital I learned that the lamented T. Spencer Wells had been a surgeon in the Crimea, after which he became general surgeon to this hospital; there was a separate gynæcological department with which he was not connected. The same arrangement exists still, and his successors, like Wells, do general surgery, but have all laparotomies assigned to them, the gynæcological department doing no laparotomies, though it does do vaginal hysterectomies, which appear to be performed only for cancer. They evacuate pus through the vagina when they can get fluctuation from below. One of the surgeons of the Samaritan Free said to me: "Spencer Wells reduced the mortality of ovariotomy from one hundred per cent. to thirty-five per cent. before Lister taught us how to

be clean. After that Wells brought it down to seven per cent., and now we have it down to three per cent. in this hospital."

In London comparatively little chloroform is given, ether being more in use than even in the North and East in the States. The A. C. E. mixture is preferred by many. At the Samaritan I noticed the giving of a combination of nitrous oxide with ether. It acts nicely and is highly extolled.

The surgeons of London, like those of Paris, wear long finger nails, and, like their French neighbors, operate in chillingly cold rooms. Except for the smoke, I could have been comfortable in the London operating-rooms with my overcoat on. Open and smoking fireplaces did not disturb the Londoner—smoke and fog perhaps never do.

From London I was taken by rail nearly eighty miles to Southampton, where I boarded the *Kaiser Wilhelm der Grosse* for New York, reaching Sandy Hook in five days and eighteen hours—the greatest speed ever attained by this or any other ship.

At Washington I recall the ten thousand miles travelled from summer until summer, and that my route included cities farthest advanced in art and many of the sciences—among cities having the wealthiest inhabitants known to man, cities the largest on earth. But as I travel up toward my domicile I am impressed with the pleasing certainty that here are the widest, smoothest, and cleanest streets of any city and draped with more leafy trees, and here are more numerous parks in verdure, flower, and fragrance than elsewhere, and over all I hear the rustle of the whitest of gowns, which were to me never so enchanting as now. Here on the banks of the wide and placid Potomac, with its pure air and sky, is the capital of the happiest and greatest of all peoples, and this capital I write down as easily the lily of the cities of the world.

J. Preston Miller, M.D.

Diphtheria in Holy Water.—Professor Vincenzi, of the University of Sassari, has investigated the holy water from "one of the most popular churches" of that city, with the following results: A single drop taken a few hours after the water was renewed and spread upon gelatin yielded in forty-eight hours about twenty-three hundred and fifty bacterial colonies, including besides those common in water bacillus tetragenus and staphylococcus albus. This drop was taken on a Saturday evening, when the water had been little used. The next evening, after numerous and crowded services, each drop of the water tested yielded innumerable colonies. Among these were numerous specimens of the bacillus coli, and others which Professor Vincenzi identified with the bacillus mucosus of Abel, believed by some to be the exciting cause of coryza. But the most important discovery was that of bacilli which in microscopic appearance, result of cultivation, and action on animals were, according to our author, undoubtedly identical with Loeffler's bacillus diphtheriæ. Four cases of diphtheria were notified at Sassari while these investigations were proceeding, and, it being the custom there for persons to touch their lips as well as other parts with holy water, the possibility of infection is obvious. "The notable number of colonies of bacillus mucosus perhaps stands in relation to the fact that contact between fingers and nose is frequent, whence it is not improbable that the bacilli are directly carried into the holy water." The bacillus coli, though possibly directly introduced, was, according to Professor Vincenzi, probably present in the church dust, which, he remarks, was copious.—*Archivio per le Scienze Mediche.*

The Liquefaction of Hydrogen and Helium.—The scientific world was thrown into a great state of excitement last week by the announcement that Professor Dewar, of the Royal Institution, had at last succeeded in liquefying hydrogen and helium. The event is regarded as one of the very highest scientific importance. Many attempts have previously been made to liquefy hydrogen, but hitherto without success, the great difficulty being the extraordinary degree of cold that is necessary for the operation. It is difficult for the untrained mind to conceive the temperature at which hydrogen liquefies. It is not very far above that of space, or minus 273 C. It is stated that it is the lowest temperature yet observed. To produce such a temperature very elaborate apparatus is required. In no place on the face of the globe is there to be found so low a temperature as in the vat in the laboratory of the Royal Institution. What the scientific results of Professor Dewar's discovery will be, it would be hard to predict, but it will undoubtedly prove of enormous importance in placing a new and potent instrument in the hands of scientists which they have hitherto found lacking. All Englishmen will rejoice that the demonstration that all gases can now be liquefied adds another to the long roll of illustrious discoveries which already stand to the credit of British science.—*Sanitary Record.*

Even Temper Necessary to a Successful Physician.—I suppose the most obvious quality that a would-be successful medical man should have is the control of temper. No doubt a certain section of humanity can make allowance for a bad temper, and a smaller section seems to like being abused; but I doubt if any one who has a bad temper can say he never lost a patient by it, and I will venture to say he must have frequently blundered in diagnosis simply by reason of his temper. How often have we to elicit the truth from a person who with all the will in the world is unable to undergo a cross-examination. The poor and uneducated are not well able to clothe their thoughts with language; they are also fond of lugging in big words, which they employ wrongly, and of course they misunderstand long words if we employ them. We thus create a situation which demands patience. —Dr. Mahomed in the *Medical Magazine.*

The Frugal Spanish Soldier.—According to an English journal, the Spanish soldier is a frugal liver, his commissariat allowance being two meals a day—one at 9 A.M., the other at 5 P.M. In some corps coffee and soup are served out in the early morning. A pound and a half of bread a day constitutes the government ration; any food beyond this must be bought by the private at the canteen. He gets little meat, and keeps in excellent condition on a chunk of dry black bread, a little oil, and a clove of garlic a day. If to this he can add a pint of wine, which tastes like vinegar and water, he feels happy. There is one thing he cannot go without, and that is his cigarette.

Stature Statistics.—The different countries of Europe vary greatly in the average stature of their people. The Scotch are the tallest, averaging 5 ft. 10 in., on a level with the Polynesians and Armenians. At the other extreme are the southern Italians, French, and Spaniards, all the shortest people, except the dwarf tribes of Africa. The average height in Ireland is 5 ft. 9 in.; in England and Scandinavia, 5 ft. 7 in.; in Wales, Germany, and Denmark, 5 ft. 6 in.; eastern France, 5 ft. 5 in.; Spain, Switzerland, northern and central Italy, 5 ft. 4 in.; Portugal and southern Italy, 5 ft. 3 in.

THE MISUSE OF COLOSTOMY.

BY CHARLES B. KELSEY, M.D.,
NEW YORK.

IT is now about fifteen years since Bryant, in a strong article in the *British Medical Journal*, called attention to the futility of all the usual methods of treatment of old and incurable non-malignant ulceration of the rectum, and advocated colostomy as the proper therapeutic measure for its relief.

The condition is that one so generally known as "syphilitic stricture" in either sex, and its real pathology need not be entered upon for the purpose of this article. The chronic inflammation with its thickening and contraction, and the consequent pain, tenesmus, discharge, and emaciation, are familiar to all. Whether the disease in any particular case be a proctitis due to catarrh, dysentery, tuberculous deposit, or venereal disease, makes no difference in the treatment now to be advocated as a substitute for that advised by Bryant.

Bryant's advocacy of colostomy as the proper treatment in all these cases could not, in the light of the surgical remedies then at our disposal, fail to carry conviction; and his ideas were enthusiastically adopted by myself and advocated to the best of my ability. The advance was bold and a little startling, inasmuch as at the same moment it relegated to the past all our former methods of treatment, such as dilatation and division of the stricture, and substituted for them an operation at that time rare and regarded with great aversion both by the profession at large and by the laity.

The teaching has borne full fruit. The profession has adopted his treatment almost as a routine practice, and what was before a surgical curiosity has become perhaps too sadly common—that is, men and women with a permanent artificial anus.

And yet the treatment was never an ideal one. It is never curative, any more than dilatation and incision had been before it; but it gives relief, and it was better than anything else known at that time. But the relief is only partial and at terrible cost in deformity and future comfort. The patient gains in health and strength from relief of pain and tenesmus, but the disease is still there, still continues to discharge pus and blood, and often, as a result of the operation, from two openings instead of one.

Such a condition is far from a cure, and does not to my mind appear as a great surgical triumph. The artificial anus is generally a source of constant annoyance and requires constant attention. The bowel is liable to prolapse, ventral hernia as a result of the incision is not uncommon, and erosion or ulceration of the exposed mucosa is often present.

When a patient knows that he or she is dying of a cancer, the relief given in this way is gratefully accepted; but when, on the other hand, patients find themselves doomed to this sort of thing for perhaps a long life, and for a condition which was not in itself fatal, they are apt, after the first relief has been gained, to ask if something better could not have been done or may not yet be done. I have had many such applications from those upon whom the operation has been performed—often, I cannot but think, too hastily and without sufficient consideration.

Since Bryant wrote, great advances have been going on in the surgery of the pelvis, and the simple question now is whether in all this class of cases we cannot take another step forward by substituting complete extirpation of the diseased bowel for the formation of a permanent artificial anus as recommended by him at that time.

It must be remembered that at the time Bryant wrote extirpation of the rectum was in its infancy. We had only the old operation from the perineum upward, attended by its well-known hemorrhage, shock, general absence of precision, and great mortality—an operation never undertaken except in cases of cancer, and not particularly successful in these.

Since then Kraske's operation from behind has grown to full perfection of technique, and has become as much an operation of precision as abdominal hysterectomy, attended by no greater hemorrhage or shock, and by no greater mortality at the hands of experienced operators. Nevertheless this fact has as yet made no impression upon the rule of treatment of these cases with the majority of the profession, and patients who, I cannot but think, might much better have been cured by excision of the diseased part are daily given up as incurable and subjected to colostomy as a palliation.

I have been as pronounced an advocate of colostomy as any man could well be, both in my practice and teaching, and this because in inoperable cancer of the rectum it is simply invaluable as a therapeutic measure; but I have come to limit its applicability to inoperable cancer, and in all other cases, whether of malignant or non-malignant ulceration, to recommend a direct attack upon the disease itself through the posterior incision. And this is the rule of practice which I believe should be generally adopted as more surgical than merely tapping the bowel above the disease through an abdominal incision. As regards malignant disease, the correctness of this treatment is admitted. May not the same treatment be extended with advantage to non-malignant ulceration and stricture?

The question between the two operations must be settled in the light, first, of the comparative danger to the patient; and second, in that of results as to subsequent comfort.

As to the comparative danger, there is no question that colostomy has the advantage, and it is simply on this account and because the operation is manually easy of performance that it has become so universally adopted. And yet, although excision has the higher mortality, that mortality is nothing like what it was a few years ago. In my own last twenty-five cases, I have lost but one, and that was one which I least expected to lose, the patient dying of a weak heart which never regained its proper action after she was taken from the table, although the operation was fully completed in half an hour and not eight ounces of blood was lost.

In my last case the patient's pulse and temperature never went above 100, and she was convalescent and sitting up at the end of the second week, the entire wound having healed by first intention, except at the point of drainage. There was no shock attending the operation and no hemorrhage to speak of, perhaps six or eight ounces. In general it may be said that the high death rate formerly attendant upon excision has become a thing of the past with operators of experience. As simple an operation as colostomy it never can be, but it is now an operation from which the patient may be expected to make a good recovery, and the death rate of which is not great enough to contraindicate its performance in cases in which it seems to offer the best results. This has been accomplished only by years of attention to technique by many operators, and hence its substitution for the simpler operation of colostomy has become possible, which was not the case ten years ago, when the mortality ranged from ten to thirty per cent. Exactly what the mortality now is it is impossible to express in figures, so much depends upon the operator, but I should think five per cent. might be a fair estimate for any recent series of cases performed by one familiar with the operation.

As to the comparative comfort of two women—one of whom has an ulcerated rectum together with an artificial anus in the groin, and the other of whom has had an excision with the formation of a useful anus in the perineum—there can be no discussion.

It has taken me personally a long time to come to this conclusion, because it has been necessary in order to reach it to follow the operation of Kraske from its original conception through all its modifications down to the approved technique and results of to-day. At one time I was quite in doubt whether the result as to comfort from extirpation began to compensate for the increased risk, but this was when the mortality was still high and when we were in the habit of forming a sacral artificial anus to lessen that mortality. Between an artificial anus over the sacrum and one in the left groin there was not much to choose; certainly not enough to pay for great additional risk in securing the former.

But no operation perhaps in surgery has improved more during the last few years than this one, and whereas a few years ago we were satisfied if the patient merely recovered, and paid comparatively little attention to the condition of the parts—the operation being undertaken almost exclusively for cancer—we now expect recovery and devote a great deal of attention to subsequent deformity and comfort.

As to the class of cases in which extirpation is indicated, it is safe to say that operation should be advised in any case as soon as it is found that the disease will not yield to skilful local treatment. But this is a very broad statement. Local treatment accomplishes much or little according to how it is carried out, and an ulceration which is incurable for one practitioner will sometimes yield at the hands of another. Many, however, can be seen at the first glance to have resulted in such a degree of change and destruction as to make all hope of healing out of the question, and as soon as this is determined operation should be advised to prevent further spread of the disease and impairment of the general health. After stricture has once formed, or after the mucosa has been destroyed and the other coats of the bowel have become infiltrated and thickened, it is useless to go on with topical applications, with bougies, and with occasional divulsions and nickings, until the sufferer is worn out with pain and loss of sleep and is ready to submit to anything, no matter how serious. The hopelessness of such treatment should be plainly pointed out to the patient, and the radical operation proposed.

Again, early operation means easier operation and less injury, less subsequent deformity, and better functional result.

As to the technique of the operation, it is not perhaps too much to say that there is hardly a more difficult one in surgery. But because this is so, and because colostomy is correspondingly easy of performance, is no valid argument in favor of one or against the other. Not only is the operation difficult, but it cannot be done by any surgeon, no matter how skilful, as well in his first series of cases as in his second, and the more he operates the less will be his death rate and the better the functional result.

I have elsewhere described very carefully the technique as practised by myself, and have illustrated it with posterior views of the anatomical relations in both male and female, but a general outline of the operation may be of assistance as embodying the results of practical experience.

All trap-door and flap incisions have given place in my own practice to a straight cut, beginning to the left of the median line at the promontory of the sacrum, slanting to the median line at the middle of the sacrum, and thence continuing straight down to the posterior margin of the anus. The attachments of the gluteal muscles and sacro-sciatic ligaments to the left side of the lower part of sacrum are rapidly severed, and the last two sacral vertebræ are cut off with heavy bone forceps, the amputated portion of bone being excised. This may require half an hour or two minutes, depending entirely upon how a man works and how familiar he is with the operation. It may, in fact, be compared to the incision down to the peritoneum in an ordinary laparotomy, and the next step in either case is the opening of the peritoneum. This is much more difficult from behind than in front, because in front the serous membrane cannot be avoided, while behind it sometimes can be found only after a considerable search, on account of the amount of connective tissue covering it.

When the sacrum has been removed the posterior surface of the rectum is directly in view. This should be still farther exposed laterally with the fingers, and the bottom of the pouch of Douglas should then be looked for at the upper right-hand angle of the deep wound. Scissors and forceps will aid in this search, and when once the fold is opened the appearance is exactly the same as when it is opened in front, but several nicks in different points may be necessary before this is accomplished, and it is not difficult to cut into the bowel itself in the effort, which is an unfortunate accident, not because it injures the gut, but because it is sure to foul the wound.

When once the index finger has entered the pouch of Douglas on the right-hand side of the rectum, it should be hooked around and under the gut and an effort made to force the way to the surface of the wound again on the left-hand side of the gut. This involves a second opening in Douglas' pouch, made by and for the exit of the end of the finger, and often the peritoneum will be found so strong and resistant that the finger nail must serve as a guide for the scalpel before it can be pushed through. The object is to get the finger into the peritoneum, under the gut, and out again on the opposite side, thus isolating the gut in great measure and making further work possible; for the strongest attachment of the rectum and the one which most seriously interferes with any effort to bring it down to the skin is this peritoneal fold between it and the bladder in the male or the uterus in the female.

Having cut the peritoneal fold and thus freed the bowel anteriorly, the next step is to divide its posterior mesenteric attachment, and this was formerly the cause of the severe bleeding attendant upon the operation; but no bleeding is necessary if the tissue is tied in

sections before being divided. A Cleveland ligature carrier will assist in this, and the division should be made as far from the bowel as possible, in order to leave the gut surrounded by as much connective tissue and as well supplied with blood-vessels as possible. Cases differ greatly in the length of the mesenteric fold and the amount of tissue between the gut and the hollow of the sacrum, but when the bowel can be loosened from its bony attachments, and still remain covered by a large amount of fat and tissue, it has a much better chance of escaping sloughing than when it lies in the hand stripped and clean and in great measure devitalized.

This is a point always to be carefully aimed at, but one which will sometimes be impossible of accomplishment, on account of the little connective tissue between it and the hollow of the sacrum.

I have said nothing about the previous preparation of the patient, but the anus should always be closed by a plug of iodoform gauze before the operation is begun, and it is a good thing to sew this into the rectum by a purse-string suture around the anus. In this way all escape of intestinal contents into the wound is avoided.

The attachments of the rectum above having been loosened, the next step is to dissect it from its attachments to the levator and the anus, and this should be done boldly and rapidly, only avoiding the vagina and bladder and unnecessary sacrifice of the anus.

The gut, in the form of a closed sac, now lies free in the hand, and before it is cut across the wound should be cleansed of all blood clots, the peritoneum flushed with hot water, and any small hemorrhages controlled. The wound is then carefully protected with gauze or sponges, and the gut cut directly across above the ulcerated part. Two or three sections may be necessary before healthy mucous membrane is reached. The cut end of the bowel is next attached by careful suturing to what remains of the anal structures, a gauze drain is inserted into the peritoneal cavity and brought out about the middle of the skin incision, and the incision is closed above and below the point of drainage with interrupted sutures.

Although it is difficult to imagine trying to do work upon the uterus and adnexa by this incision as the one of choice, none the less when once the pelvis has been opened by this route such work is not difficult. I have grown into the habit of examining tubes and ovaries in every case of the operation upon women, and doing any work which seemed strongly indicated, such as the removal of a pyosalpinx or hydrosalpinx or a cystic ovary.

Such in general terms is the operation I believe to be indicated for the treatment of non-malignant ulceration and stricture of the rectum. There are many modifications of it, and many complications may arise in its performance which the experienced operator will be ready to meet, but its after-results will be found much more satisfactory than those attendant upon colostomy. The operation is not followed by "good sphincteric control," any more than is colostomy, but the anus is where nature placed it and often of enough power to prevent a solid passage for sufficient time to seek the closet. The deformity is often no worse than is seen to follow operations upon extensive fistulæ, and the result as to function fully as good.

Atropine has been found by Traversa's experiments to have a constipating effect; hence in conditions of atrophy of the intestines belladonna and its alkaloids should not be used, as they now so largely are in anti-constipation pills, etc. In lead colic, on the other hand (a spasmodic condition), atropine is indicated. —*La Semaine Médicale*, January 22d.

A CLINICAL CONSIDERATION OF HERPES ZOSTER.[1]

By LEONARD WEBER, M.D.,
NEW YORK.

THERE is not much to be said of an ordinary case of shingles that comes and goes in a week, disturbing the patient but little, and leaving him as well as he was before. However, among a comparatively large number of cases of herpes zoster which were under my care I have notes of a few, the treatment of which required considerable time and needed definite remedies to deal with local inflammatory conditions, as well as to overcome the consecutive and severe neuralgias associated with the disease. It is on account of these complications, of equal interest to the practitioner and to the neurologist, that I desire to bring the subject before you.

We may define, or rather describe, herpes zoster as an acute inflammatory disease of the skin, consisting of groups of vesicles on an inflamed base, distributed along the course of a cutaneous nerve. It is usually unilateral; bilateral cases must be very rare. I have seen only one of herpes intercostalis in a rheumatic subject. Kaposi, Eulenburg, and others have observed cases of that kind.

Inasmuch as diseased conditions of the ganglion Gasseri, also of lumbar intervertebral ganglia in herpes zoster, have been seen and described by Baerensprung, Kaposi, and others, there can be no manner of doubt that ganglionic disease, parenchymatous, hemorrhagic, or otherwise, may be and often is the cause of shingles. Clinical observation shows, however, that this is not the origin of every case, but that disease in the spinal cord itself may produce it, as in bilateral cases, and that it may also be caused by disorder of peripheral nerves. Frequently, for instance, herpes zoster does not follow the entire course of a nerve, but appears only along the most peripheral part, or even a branch of the same. Again it has been seen in the territory of nerves that were in a state of irritation or congestion through wounds, abscesses, or tumors in their immediate neighborhood. There are also numerous reports of cases of herpes by various authors in which nodular perineuritis or interstitial and parenchymatous neuritis has been demonstrated in the affected nerve branches.

From all observations it must be concluded that herpes zoster is produced by a disease of a nerve, either at its point of origin or in the vertebral ganglion, or somewhere along its peripheral course, and that the appearance of the herpetic eruptions always corresponds to the anatomical course of the nerve. As to the order of frequency of development in the various regions of the body, I may state that, as far as my own collection of about twenty-three cases of herpes zoster is concerned, the largest number of them were pectoral; after these come cervical and cervico-brachial, then facial, then abdominal, and finally odd cases about the scalp and thigh. The majority of the patients were not in good health when attacked, rheumatism, renal disease, uric-acid lithæmia, neurasthenia spinalis, or tabes being noted in them. The single case I saw of herpes gangrenosus, in the postauricular region of the occipitalis magnus branch of the third cervical, concerned a tall, stout, and vigorous man, of forty-four years, who was very nervous and excitable, but appeared to be in general good health. On the other hand, the case of bilateral intercostal zona—during the first week of this illness on the left, during the second week on the right side of the thorax—accompanied by severe neuralgia, which, fortunately, did not persist long after the disease had run its course

[1] Read before the American Neurological Association, May 27, 1898.

of three weeks, concerned a girl of twenty-eight years, who has been the subject of repeated attacks of articular rheumatism, and never had good health.

With regard to the progress and symptoms of the disease I have not observed anything which is not already described in the text-books, but there are some points connected with the prognosis that require special notice. I have found it to be true that, apart from the amount and severity of the eruption, the gravity of herpes zoster is in proportion to the age of the patient. In children and young persons as soon as the pustules have healed, the patient is generally quite well, and no trace of the disease is left except perhaps a few small scars and a slight tenderness of the skin. In the middle aged, and still more in old people, this is not the case. The eruption is almost always followed by some form of nerve disturbance, generally severe neuralgia, which may last for many weeks and months; especially so in facial herpes. Other sensory disturbances and muscular atrophy may also occur. Vertigo is also mentioned among the sequelæ, but I have not noted that or muscular atrophy in any of my cases. In very old people an attack of zona may be a serious affection, from the consequences of which they will often not entirely recover. Another point of importance which should be borne in mind is that facial herpes, particularly supra-orbital, is very apt to leave deep depressed scars. The patient should be warned of the possibility or probability of such occurrence, otherwise he may attribute the formation of such scars to neglectful or injudicious treatment. But he should also be warned not to bring his dirty fingers in contact with the vesicular eruptions, and be directed to dress them with something better than stale and rancid zinc ointment. There can be no manner of doubt that the suppuration of the vesicular eruption is often due to secondary (streptococcus) infection, that this may spread in breadth and depth in vulnerable individuals, and that it should, and can, be generally prevented by scrupulous cleanliness and the usual methods of aseptic wound treatment. It is almost a matter for surprise to see most people go on maltreating blisters, sores, ulcers, and the like, with dirty poultices or stale zinc salve, after they have learned pretty well to wash a wound clean, cover it with iodoform gauze, and close it up with a strip of plaster.

For local treatment of zona I prefer at the outset a dry application of bismuth subgallate and talcum in equal parts dusted over the affected part and sterilized gauze to cover; but a few changes of such dressings will be required in ordinary cases. When the burning heat is considerable or the patient finds no comfort in the dry dressing, subnitrate of bismuth, one part, to cold cream, three parts, will be found a quite satisfactory ointment to spread on the lesions, to be continued until healing has taken place. For the dread neuralgias after herpes I have seen better results from ten to fifteen-grain doses of quinine, given two or three times a day for a week, than from any other remedy. Hebra, Kaposi, and others have recommended rapidly increasing doses of Fowler's solution of arsenic. My experience with heroic doses of arsenic in chorea and pseudo-leukæmia have been discouraging; the after-effects of large doses of the poison upon the system may even be serious. I have had no need of it in this disease. In one case of neuralgia after cervico-brachial herpes in an old man with sclerotic arteries I had good success with iodide of potassium, gr. x. to xx. t.i.d., and strychnine, gr. $\frac{1}{30}$ t.i.d., continued for a month. In watching the progress of this case I noticed that the œdema, stiffness, and tenderness of the integuments began to yield a week after the patient had begun taking the iodide, and improvement in his neuralgic sufferings followed soon. In the neuralgic stage the patients are wonderfully sensitive to even slight changes of temperature or motion of the affected parts. If we mean to cure, we must keep them very quiet, in even temperature, feed them well, and order everything pertaining to restoration of normal bodily functions very carefully, aside from the treatment by drugs.

Of the cases treated by me three may be selected as being out of the normal.

Case I.—C. M——, aged forty-three years, single, merchant, tall and very stout, very nervous and excitable man, no taint, came to me with herpes in the territory of the left occipitalis magnus, that had broken out with the usual symptoms of constitutional disturbance the week before. There were three or four small but rather deep ulcers above the mastoid process and superficial gangrene of the cutis upon and by the side of the mastoid. Prior to the development of necrosis the patient had noticed confluence of the whole group of pustules in the locality mentioned; though he experienced no great pain or discomfort, he became frightened by the black appearance of the slough and sought medical aid. After the dead tissue was cut away, the wounds were dressed with iodoform and gradually healed. Neither during nor after the attack did he suffer from neuralgia or other local disturbances.

Case II.—Miss C. A——, aged twenty-eight years, rather delicate but active and bright girl, has had a number of attacks of acute and subacute articular rheumatism during the last six years. Last January, and after a mild attack of rheumatism, she had right intercostal zona, and on the tenth day from its first appearance, and before healing had taken place, the same occurred on the left side, both attacks following the eighth intercostal nerve. The patient was troubled with pretty severe neuralgia while the disease lasted, three weeks, and for about three weeks thereafter when it ceased. The treatment consisted in twenty-grain doses of sodium salicylate t.i.d., with occasional morphine injections in the acute stage, and was followed by iodide of potassium, ʒ ii.; liquor potassæ, ℥ ss.; aqua, ℥ viii.— ℥ ss. four times daily from the fourth week on, to be continued until the pains ceased. This is the case I venture to call bilateral, though some objection may be raised to this appellation, inasmuch as the eruption did not affect both sides simultaneously, but after an interval of ten days.

Case III.—Mrs. T. T——, aged sixty-four years, widow, looking older than her age, but physically strong and active; no history but chronic constipation. Last February she had a severe febrile attack of left facial herpes, involving nearly all the cutaneous branches of the third division of the trigeminus, with large and small eruptions upon the left under lip, cheek, temple, auricle and anterior part of meatus, and scalp, with considerable swelling and tenderness of integuments, intense redness, and some œdema of the mucous membrane of the lip and cheek; the left side of the anterior portion of the tongue was also swollen and tender, and the papillæ were prominent, giving the part the appearance of the raspberry tongue of scarlatina. The local and constitutional disturbances in this case—fever and inflammation—lasted three weeks. Though there were much discomfort and suffering from inflammatory pain, neuralgic symptoms did not set in until the fourth week, when the eruptions had almost healed, but some tenderness and œdema of parts remained. They came on furiously, darting through the left side of face, ear, and scalp, and were particularly severe in the course of the lingual nerve. The paroxysms occurred about every two hours at first, lasting from ten to fifteen minutes. In the intervals the patient was not free from ache and pain, but they could readily be borne. Opiates and soothing applications were freely administered,

but they gave temporary relief only. No improvement took place until the end of the fifth week, and after I had put the patient thoroughly under the influence of bisulphate of quinine, of which she took fifteen grains t.i.d. for six days. Then there was a decided amelioration in the severity and frequency of the attacks. During the sixth or seventh week she was ordered fifteen grains twice daily; after that the paroxysms ceased and gave place to an aching soreness in the parts affected, which persisted for some weeks and is not yet entirely gone.

It was a matter for some surprise to me that while the suffering lasted the patient bore opium and quinine equally well, while some years ago, when I had occasion to treat her for intermittent, she was not by any means so tolerant to quinine. At the turning-point of the neuralgic disorder I showed the patient to Dr C. L. Dana, who advised strychnine in full doses if she should relapse; happily she has not done so. For a week or two the left side of her mouth and tongue could not bear the touch of anything, and I had some difficulty in feeding her. Absolute rest, quiet, even temperature of room, and good nursing also helped greatly toward recovery in this case.

Although herpes zoster may attack persons in previous good health after prolonged exposure to cold or after unwonted and severe exertion, I believe that acute and chronic infectious diseases as well as gastro-intestinal auto-infection play also an important part in the etiology of the disease. It is but two weeks since I saw a case of zona of the shoulder in a young man who had recently had scarlet fever. For the successful treatment of herpes neuralgia, quinine in large doses, two or three times a day and continued to the point of tolerance, is probably the best remedy we have; the iodides and strychnine and the galvanic current, when applicable, can be ordered after quinine fails, but careful nursing and management are highly important adjuvants in the successful treatment of every severe case.

25 West Forty-Sixth Street.

A CONTRIBUTION TO THE SYMPTOMATOLOGY AND DIAGNOSIS OF CHOLELITHIASIS IN INFANCY AND IN CHILDHOOD.[1]

By A. V. WENDEL, M.D.,
NEWARK, N. J.,
SURGEON TO THE ALEXIAN HOSPITAL.

If our theories concerning the predisposing factors in the genesis of biliary calculi are correct, it is surprising that civilized mankind are not all afflicted with gall stones. The assiduous application of a tight abdominal binder to the infant from its birth to the eighteenth month or longer—which immobilizes the abdominal walls, compresses the abdominal contents, and hinders the physiological descent of the diaphragm—would seem a most effective method of inducing biliary stasis and favoring the invasion into the biliary passages of pathogenic micro-organisms. Fortunately the extreme activity of the digestive and respiratory systems in infancy counteracts the malhygiene inflicted upon the helpless creatures by their good mothers, and thus saves us from universal cholelithiasis.

But, although cholelithiasis in adult life has received such careful attention that an adequate review of the accumulated literature taxes one's time and patience, on the other hand, reference to the current pædiatric literature and handbooks gives but little information concerning the occurrence and clinical evidence of this disorder in infancy and childhood; indeed, most of the older writers believed this period of life exempt.[1] The impression prevailing in the professional mind as to the extreme rarity of cholelithiasis in children is no doubt dependent upon several causes. Fiedler[2] claims that gall stones are very frequently overlooked in post-mortem examinations. Naunyn[3] believes the statistics of institutes unreliable, because the various periods of life are unequally represented. Mayo Robson,[4] when referring to the general statistics of cholelithiasis, thinks the figures too low, because they were taken from the laboring classes, who, he believes, are not very subject to gall stones. These statements probably explain the discrepancies met with in the literature. Thus Valleix claims that gall stones are even very frequently found in the newly born. Fauconneau-Dufresne's ninety-one cases included four infants. Cyr declares that he found calculi only twice in individuals under ten years old in five hundred and fifty-eight cases; Wolf, once in forty-five cases; and so on.

In six autopsies upon infants at the Maryland Maternity during the year 1888, we found gall stones once. The subject was an eleven-day-old infant, whose death had resulted from an injury to the head. Ninety small cholesterin calculi were taken from the gall bladder, one was located in the cystic duct, and three were found in the upper portion of the duodenum. We presume that the stones were expelled *in agone*. During the year 1889 gall stones were observed three times in twenty-nine autopsies performed by the writer at the Nursery and Child's Hospital of Baltimore.

The size of calculi in children varies within wide limits; we have seen them as small as grains of sand. The large one we exhibit to you is about one and one-half centimetres in diameter, and was removed by operation from the gall bladder of a six-year-old child. They may attain considerable size.[5]

This paper is based upon the careful observation of sixteen cases, occurring in persons under eight years of age. The diagnosis was in each case corroborated either by detecting the calculi in the intestinal evacuations or on the operating-table, and in two instances by autopsy.

Another reason why so little is heard of cholelithiasis affecting children during life must be because we are dependent upon the phenomena of pain for its syndromology; and, considering the very frequent occurrence of painful disorders of the gastro-intestinal system in children, also that as a rule the practitioner contents himself with a superficial inspection of the alvine and urinary evacuations, it is easy to discern why cholelithiasis may be overlooked. Several of the cases of gall-stone colic under observation had been diagnosed as "a cross child," "fits," and "severe wind colics," one even as peritonitis. In children over eight years of age the symptoms are very much the same as one observes in adolescents; but children under that age, and particularly those under three years, we believe present a distinct symptomatology. No attempt has been made to cover the entire field of cholelithiasis, because some features are the same as in older subjects, and we have not met with all the types prevailing; our intention is to bring this subject to your notice to encourage a more extended investigation.

The importance of a correct diagnosis is also not merely one of personal satisfaction to the physician, as the well-being and future efficiency of the patient

[5] Saye (Journal des Savans, September, 1697) reported an instance in which he found a gall stone as large as a hen's egg in the gall bladder of a twelve-year-old child.

may depend upon the early recognition and removal the predisposing factors. To the surgeon it is certainly one of importance, because an obstructed cystic duct, common duct, or ulcerated gall bladder is as much a surgical disorder as a diseased appendix vermiformis. Successful operative intervention in cases presenting serious complications will also be in proportion to its promptness and early application.[1]

With the clear indications of the present day, only those hesitate who lack the confidence resulting from a correct and comprehensive diagnosis. The high mortality attending prolonged and complicated delayed peritoneal operations upon children should be an additional incentive to early diagnosis.

For the purpose of clinical convenience we shall describe the symptomatology under the following captions:

I. Cholelithiasis with intermittent obstruction of the bile passages (typical gall-stone colic).

II. Cholelithiasis with hydrops cystis felleæ.

III. Cholelithiasis with cholecystitis, but without active symptoms of obstruction (empyema cystis felleæ).

IV. Cholelithiasis with perforation of the gall bladder and extravasation into the peritoneal cavity, with peritonitis.

V. Cholelithiasis with lodgement of calculi in the common duct.

As in adults, concretions often exist without symptoms. In the four autopsies already recorded, as far as we know, symptoms were never manifested which indicated their existence.

Cholelithiasis with Gall-Stone Colic.—The physician will generally be consulted after the second or third attack, as the first is very apt to be regarded as due to some digestive disturbance. The mother or nurse states that the little one was taken with a crying-spell which she was unable to account for, and which did not cease notwithstanding applications of every conceivable remedy in the house. The paroxysm may have lasted several hours, the patient then enjoying repose, only to be followed by another severe crying-spell of variable duration. Often she will bring a napkin stained with a deeper tint of urine than usual, or, if the child be old enough to use a chamber pot, she will call attention to the darker hue of the urine. Question will always elicit the information that this change of color followed the attack by at least several hours. The biliary obstruction has been so slight that very rarely will there be any tint in the skin. This type corresponds to the passage of small calculi, and unless the stools be very carefully examined they will not be found.

II. The second type may be called characteristic, and is usually observed in children between two and eight years of age. A child apparently in good health becomes pale, vomits, and then begins to scream. Nothing can calm the little one; it clutches its mother or nurse from fright. Another one may repel any advance, instinctively fearing injury. By this time the practitioner has generally arrived on the scene. The information is volunteered that no offending pin can be found, but that it must have ingested something which has disagreed. If then the attendant quietly observes his patient for a few minutes, he will notice that the child is very restless, that it frequently presses the hands against the epigastrium, vomits, and complains bitterly of pain. It will be also noticed that the few moments of crying are regularly interrupted by severe vomiting. If the paroxysm be a mild one, after a variable duration of the phenomena mentioned the child quiets down and falls asleep, to awaken refreshed or perhaps to pass through the same ordeal. In severe attacks the face soon exhibits the effect of suffering by the sinking of the orbital tissue, the cold perspiration, and in attacks of three or four hours the nasal line of Jadelot develops. After an hour's duration the temperature will generally be found from 100° to 101° F. The pulse was always increased in frequency in our cases. The fæcal dejecta will often show the ordinary aspect of acholia, but sometimes, be it remembered, acholic evacuations are of a green color in children. The urine becomes biliary in from six to twenty-four hours. After the culmination of the attacks tenderness can be detected by palpating the region of the gall bladder in the manner which will be described later.

III. The third type is most common in the young child and infant and in neurotic children. The onset is ushered in by a convulsion, which may repeat itself with alarming frequency and even prove fatal. Generally the seizure is interrupted by severe vomiting and crying is interrupted by the eclampsia. The real nature of the disorder occurring in a child without previous observation in similar attacks will rarely be recognized until after it has ceased, and then only by examining the gall bladder for tenderness and the dejecta for the characteristic changes. In one case we noticed that severe crying was followed by severe emesis and then convulsions, the temperature being found normal; the condition was very suggestive of cholelithiatic spasm, and subsequent observation corroborated the diagnosis. The temperature will be found normal at the beginning, thus differing decidedly from the eclampsia of digestive disturbance.

Hydrops Cystis Felleæ.—The following case is so typical that we will quote from the record instead of entering into a detailed description:

"F. J——, aged seven years four months, has never been afflicted with any of the diseases common to childhood. Had lobar pneumonia five years before consulting the writer; otherwise had never been ill until six months ago. At that time a severe vomiting-spell attended with pain in the epigastrium occurred. The attack lasted nearly a week; the patient then gradually improved, but her mother states that six weeks ago F—— told her that coughing always caused her to feel a pain in the epigastrium; also that at times the patient would place her hand upon the right hypochondrium and complain of soreness; at other times she would refer the pain to the right scapula. The tongue presents nothing abnormal, but vomiting occurs occasionally. She has always been constipated. Palpation of the abdomen reveals marked sensitiveness about the xiphoid appendix, increased by percussion; from this painful area to the umbilicus there is no abnormal sensitiveness. Palpatory exploration detects a sensitive enlargement of the gall bladder. Liver normal. No fever. Under treatment the painfulness and gastric irritability disappeared in the course of five months, but the enlargement of the gall bladder remained."

Empyema Cystis Felleæ. — I. Subacute form. Usually after one or more attacks of colic the patient, often of previous lightsome and buoyant disposition common to children, manifests a change of humor; reluctant to disport, its temper is often displayed by peevishness, even perverse and petulant conduct. The appetite may or may not be normal. A full meal is often followed by epigastric uneasiness. If the patient be stripped of the clothing and placed in the sitting-posture, the respiratory movements will be found to be more thoracic than usual; indeed, we have often noticed, after an attack of gall-stone colic leaving a sensitive and swollen gall bladder, that the

[1] "Die Resultate der Internen sind noch genau dieselben, wie vor fünf Jahren, die der Chirurgen haben sich seitdem so erheblich gebessert, dass et heute wahrlich nicht als Annektionslust, sondern als Pflichterfüllung angesehen werden muss, wenn der Operateur schon frühzeitig zum Messer greift." Kehr: Verhandlungen der deutschen Gesellschaft für Chirurgie, 1896.

occasional deep inspiration habitual to infancy and childhood is attended by a characteristic gasp and halt.[1] Pallor of varying duration and intensity followed by vomiting is very frequent, often troublesome, thus aggravating the morbosity by depriving the patient of needful alimentation. Coexistent infective cholangitis causes more or less icteric pigmentation. Intestinal disturbances are not more common than should be expected under the circumstances. The temperature may range from half a degree to several degrees above the normal, and manifests only slight diurnal variations. The continued elevation of the temperature adds its quota to undermine the health. The pulse ranges in accordance with the fever. Soon after the occurrence of cholecystitis the palpating hand detects rigidity of the right abdominal muscles. When the muscles are properly relaxed, the sensitive and swollen gall bladder may be felt. After some days the swelling often disappears, and then one has to rely upon the detection of the area of sensitiveness corresponding to the location of the viscus. Children of sufficient mental development complain of pain referred to the tenth costochondral region when drawing a deep breath or after coughing. In case occlusion of the cystic duct coexists, the signs of this complication will also be manifested.

II. Acute form. This generally occurs after a paroxysm of gall-stone colic. Whereas the patient was very restless during the attack, it now lies quiet, with generally the right leg drawn up, and objects to being moved. The cry, which has been lusty, is succeeded by the groan of distress, and if old enough it complains of severe soreness in the right hypochondrium. Breathing is decidedly costal. The temperature is from 102.5° to 104° F., the pulse very rapid. Vomiting continues, causing much distress. Delirium is nearly always present, and in one case the hyperpyrexia resulted in convulsions. Examination of the abdomen causes much pain, but careful, deliberate palpation will distinguish an indurated mass situated on the anterior border of the liver, sloping off to the middle line, and sometimes extending as low as the umbilicus. Recession of the symptoms with general improvement indicates a favorable turn, while great prostration or collapse indicates approaching death.

Cholelithiasis Resulting in Perforation of the Gall Bladder and Extravasation Peritonitis.—We believe that the histories of the following two cases give so adequate a description of this severe complication that any detailed symptomatic picture is unnecessary.

Case I.—Lucy N——, nineteen months old, white, was admitted to the Nursery and Child's Hospital of Baltimore, on May 16, 1889, in a state of collapse. The mother stated that two days before the patient had been taken ill with vomiting and diarrhœa; that several of the many intestinal evacuations were mixed with blood. As the infant was getting worse, she became alarmed and brought the little one for treatment. On being questioned closely for the previous history, the mother replied that the patient had been raised on condensed milk, and had been real good until six months after its birth; from that time on the baby had been "taking notions at times to cry all night without any reason." Troublesome constipation supervened, but she admitted that paregoric had been freely employed to quiet the crying-spells. She thought she had noticed some fulness in the right hypochondrium when bathing, and especially while soaping the abdomen of the patient the next day after several of the paroxysms. On query she also thought that sometimes the urine was darker in color, but had never noticed decided icteric change in it or the skin. The child appeared to have been well nourished, but now the face was pinched, dusky, with nostrils dilating during the rapid, shallow respiration. There was no scleral discoloration. The temperature was 98 F.; no pulse could be felt. Cardiac auscultation gave 194 pulsations a minute with arrhythmia. Abdominal distention was very marked, but as the patient was *in agone* no attempt was made to palpate the abdomen. Death occurred within an hour later.

At the writer's solicitation the relatives permitted a limited autopsy, which was performed the next morning with the following results: The abdominal cavity contained about a pint of sero-purulent fluid, which was not stained with bile. The intestines were very much distended and presented many patches of recent lymph. They contained some bloody mucus; the stomach contained nothing save some gas. Old adhesions existed between the gastro-hepatic omentum and the hepatic flexure of the colon. The gall bladder was decidedly thickened; it measured one and one-half inches in length and about one inch in breadth at the fundus. A small perforation presented upon its antero-internal surface. The viscus contained some pus and seventy-four small facetted concretions. Three more were impacted in the cystic duct. The choledochus was unobstructed. The interior of the gall bladder presented an ulcer about one-half inch in diameter, the centre corresponding to the perforation. The liver and kidneys presented nothing abnormal.

Case II.—Frank C——, aged seven years and four months, was admitted to the Alexian Hospital at 9 P.M. on June 21, 1895, suffering with severe abdominal pain. He had been taken sick quite suddenly while at play the previous morning. Said his "belly ached him," became very pale, weak, and vomited. The family practitioner referred him to the hospital for operation. The previous history stated that the patient had scarlet fever three years before. Eight months after his recovery from this disease he had a continued fever for seven weeks. Never had jaundice, but often complained (since the continued fever) of pain referred to the epigastrium, attended with nausea and vomiting. The abdomen was distended and so sensitive as to render palpation unsatisfactory, but gentle perseverance located a diffuse hardness extending downward from the anterior border of the liver to a level with the umbilicus, also inward to the median line. The thermometer registered 102.5° F.; the pulse was 130 to the minute. Constant nausea with occasional vomiting annoyed the patient. An enema brought away a normal alvine evacuation. The patient was prepared for operation, etherized, and the palpatory diagnosis verified. Thereupon the usual incision was made in the semilunar line. The adherent omentum under the site of the incision was carefully separated from the parietal peritoneum in a direction outward. Sero-purulent fluid to the amount of probably half a pint welled up and was absorbed in gauze sponges. The cavity was then enlarged, examined by the finger, and found walled off from the general peritoneum and to communicate with the gall bladder through a perforation in the fundus about one-fourth inch in diameter. Nine small stones were removed from the abscess cavity. The opening in the gall bladder was enlarged; twenty-one small polyhedral calculi and one large facetted stone about one and one-half centimetres were removed. By this time the pulse had gone to 160, although the patient had been only ten minutes on the table. The cystic duct was therefore not probed. A rubber drain was inserted in the gall bladder, and some gauze into the abscess cavity for drainage. The wound was re-

[1] Keeping before the mind that the cholecystitis from cholelithiasis generally involves the peritoneal coat of the gall bladder, evinced by the adhesions contracted with adjacent structures, and that the normal respiratory hepatic mobility (according to recent skiagraphic observations of Laborde) often equals as much as seven centimetres, the reason for and importance of this gasping halt of the inspiratory movement become apparent.

duced with silkworm-gut sutures. No bile or calculi ever passed out. The sinus gradually contracted and was firmly closed seven weeks after the operation.

Cholelithiasis with Lodgement of Calculi in the Common Bile Duct.—Dr. William O. Bailey has been kind enough to permit us to use his notes of a very interesting case.

"L. T——, female, aged six years, white, of German parentage, was first seen at my office September 12, 1894. The mother stated that she had noticed during the past twelve months that the child suffered with severe attacks of pain, and that these attacks lasted all the way from thirty minutes to fourteen hours. During these seizures the child was very restless, crying, groaning, pressing her hands into the abdomen, and complaining of the "stomach-ache." Its face had a pinched look, the features were distorted, and the extremities were cold and clammy. These attacks occurred about every three months, and each ended with a severe vomiting-spell. On examination the patient appeared well nourished and properly developed. Skin clear and moist, with no trace of jaundice. Tongue coated at the base. Heart and lungs normal. Physical examination revealed a tumor (cystic), about the size of a hen's egg, along the lower margin of the liver, which seemed to be painless, even when considerable pressure was applied. The liver showed traces of slight enlargement. Spleen normal. Abdomen somewhat prominent.

"From this date until September 8, 1897, the child has had five attacks of colicky pains. Following these attacks the tumor disappeared, but could again be mapped out quite distinctly a few days later. Careful examination of the stools after each attack revealed several small gall stones, polygonal in shape, varying in number from three to eight.

"The fifth attack began at 5 A.M., September 8, 1897, with severe pain and vomiting. Sedatives and warm applications brought relief, so that in about two hours the distress of the child had subsided and it became quite comfortable. At 1 P.M. the pain again returned with increased vigor; the child screaming, tossing about, grasping her belly with her hands, flexing the legs and thighs, and bending the body in multifarious contortions, notwithstanding the sedative freely administered. The pains continued during the following night.

"The next morning (the 9th inst.) the temperature registered 101° F.; pulse, 126. Patient jaundiced. Examination now revealed the gall bladder enlarged and the liver very sensitive. Alvine discharges showed no trace of gall stones. During the day the patient became more deeply bilious in hue and extremely irritable from severe itching of skin. The second day the paroxysms subsided. Temperature, 101.25° F.; pulse, 114.

"On the third day, September 11th, the patient more deeply jaundiced and very drowsy. Temperature, 102° F.; pulse, 128. Abdomen tympanitic. Liver enlarged. In the afternoon the child developed severe rigors, followed by profuse sweating, increase of pain, and delirium. High enema ordered, which brought away clay-colored stools.

"September 12th, symptoms all intensified. Temperature, 102.5° F.; pulse, 130. Delirium continued all night. At 12 M. met Dr. Wendel in consultation, who coincided in the diagnosis of cholelithiasis with obstruction of the common duct and infective cholangitis.

"Aware of the relative commodiousness of the common duct and the expulsive power of the bile ducts in children, it was decided to wait a little longer and and see if the stone imprisoned in the canal would be expelled into the bowel by the efforts of nature. If it failed to pass and the symptoms increased, then operative intervention was to be undertaken.

"September 13th, the fifth day, the condition of the patient remained about the same. Temperature, 102° F.; pulse, 124.

"September 14th, at 10 A.M., the child again suffered from a return of pain. Its suffering increased very rapidly and finally culminated in spasms.

"The spasms gradually subsided, the child became conscious, called for a drink of water, turned on its side, and fell into a sound sleep. From this time the temperature dropped, the pulse became less frequent, so that on the following morning there were only some soreness and enlargement over the hepatic region and gall bladder. The jaundice was entirely gone in three weeks."

Diagnosis. — Pain. The emotional and physical phenomena occurring as the result of pain are the only criteria which we can rely upon to determine its presence in very young children. It is obviously very necessary carefully to observe the actions of the little patient during a supposed paroxysm, in order to locate and differentiate the morbific cause. But the anamnesis obtained from the child's attendants must be exhaustive, thorough, and include particularly the previous behavior of the gastro-intestinal and nervous systems, the skin, and urine. Occasional crying-spells accompanied by severe vomiting should always make one suspicious of calculi, no matter how young the subject, and continued observation for corroborating data should by no means be neglected. Children between four and eight years of age invariably refer the pain of gall-stone colic to the epigastrium. One of the most valuable diagnostic signs is the sensitive state of the gall bladder remaining after the cessation of the symptoms of the colic; it is very often the only reliable one, and after the child has rested may be elicited in the following manner:

The first requisite in very young subjects is to distract the attention. Nothing is so subservient for this purpose and more agreeable to the patient than submerging the body (excepting the head, of course) in a warm bath. The warm water relaxes the muscular structures; the stimulation by the warmth relieves the lassitude resulting from the previous suffering. The former experiences of daily ablution have taught the child to expect considerable handling under similar circumstances, and therefore less objection is liable to be offered on the part of the patient to the proposed physical examination of the abdomen. While the mother or nurse soaps the child, the physician places his hand in the water that it may acquire the warmth of the surrounding medium; employing only the ball of the fingers, he will then gently stroke and depress the abdominal wall, beginning at the left side, gradually traversing the whole abdomen, and lastly approaching the region of the gall bladder. As the abdominal wall is depressed by the fingers over the immediate region of the gall bladder, there will be sudden contractile parietal rigidity induced in case the gall bladder is sensitive. Sometimes the face will be expressive of pain. Enlargement of the gall bladder may also be detected during the examination. After considerable experience with this method in many obscure cases of various abdominal disorders, we desire to call your attention to it as a most reliable means for obtaining a palpatory diagnosis in infants and in very young children. This elaborate method may be omitted in older or tractable infants. The region of the liver and gall bladder may also be satisfactorily explored by elevating the patient's shoulders to forty degrees, flexing the flexed extremities upon the abdomen, and then palpating with the left hand from below upward.

Aberrant position of the gall bladder must be re-

membered, as Siraud's[1] investigations showed that, although the usual location of this organ is fairly constant, yet deviations are frequent enough to require caution. The writer[2] has elsewhere reported an instance of a floating gall bladder which occupied in its migrations many anomalous positions in the abdominal cavity. For the purpose of differentiation, a mobile gall bladder will be found to move upon an arc the centre of which is its attachment to the liver. For topographical purposes the acromio-pubic line of Janeway has served us best in locating the gall bladder, owing to the relatively lower position of the anterior border of the liver in young children.

Rubini[3] was the first to call especial attention to pain around the xiphoid cartilage from gall stones during their expulsion. We have frequently noticed this symptom during the transition of calculi through the ducts, particularly in calculous incarceration of the cystic duct. Attention has been called to the occurrence of this symptom in one of the cases already detailed; we have observed this symptom in six out of eight cases of calculous obstruction of the cystic duct in adults, and the localization was proved by operation. Rubini's symptom certainly deserves more attention, because if extended observation should prove the reliability of it as a sign of obstruction of the cystic duct, then one of the perplexing questions in the surgical diagnosis of cholelithiasis will be rendered more easy of solution. Permanent cystic obstruction is well known often to result in serious or even fatal complications. These cases can be properly treated only by surgical intervention, and, as our diagnostic prehension of obstruction of the cystic duct is not so satisfactory as the development of the operative technique for this condition, more ought to be heard of Rubini's xiphoidal pain.

Murphy's[4] investigations would seem to militate against the assumption of attributing so much diagnostic importance to this symptom, but a little reflection will soon determine the difference between simply irritating the fundus of the gall bladder and the constant *vis a tergo* against the incarcerated calculus. In one instance (adult) this pain continued for seven weeks after the entrance of the stone in the cystic duct, but in the other cases it gradually ceased within four weeks. In gastrodynia we have observed that the maximum painful point is referred to immediately above the umbilicus. The painful area of gastritis is diffuse and localized over the lower epigastric region. Scapular pain in children we have noticed only once.

Vomiting is severe, persistent, interrupted only by the crying, and very exhausting when the attack is of long duration. We have never observed stercoral vomiting in children during gall-stone colic. The cessation of emesis is generally coincident with the extrusion of the concretion into the bowel, but it may continue with uninterrupted severity during acute cholecystitis or cholangitis.

Convulsions have already been mentioned as occurring during the culmination of the paroxysm of colic. The convulsive type proved fatal in one of our cases. No other cause could be determined; there was no fever until after five spasms had occurred. In young children vomiting attended by convulsions and without fever must always be considered as very significant of some form of colic. We believe that this variety is very often overlooked in very young children. Indeed, the practitioner will do well in every case of convulsions occurring without premonition carefully to examine, before excluding gall-stone colic as the cause.

Fever. Beyond what has been said in the preceding, we have nothing to add.

Chills were only once observed in the children under our care.

Respiration. Naunyn claims that costal breathing is rare, except when peritoneal irritation is very marked: but we have found that after an attack in young children even slight sensitiveness of the gall bladder renders the respiratory movements not only costal, but also of a jerky character when the patient is placed in the sitting-posture.

Jaundice. Our observations entirely agree with those of Waring,[5] that in young persons jaundice caused by gall stones without pain is rare. This point has been nicely illustrated in an eight-year-old male child with congenital stenosis of the common duct, complicated by sudden inflammatory occlusion, reported by Dr. R. H. Russel,[6] in which simply jaundice and no colic were observed. The energetic expulsive faculty of the bile ducts in young individuals, as a rule, does not permit the long residence of calculi in the common duct. Jaundice in those cases is slight and apt to be overlooked, unless a careful urinary examination be made. The urine may not give the reaction of Gmelin, unless it be evaporated to about one-tenth its original volume; sometimes the Gmelin reaction is absent, but then the bile acids should be tested for before concluding that there is no admixture of bile.[7] The urine of infants may be tested for bile color by dropping the acid near the border of the urine stain on the napkin, so that the two may coalesce; the characteristic play of colors will be seen even when bile is present in small quantities.[8] In all doubtful cases the urine should be evaporated upon a water bath to one-tenth and tested for bile color and bile salts. In children acholic fæces are not necessarily white; frequently they present a green color with putrid odor and diarrhœal tendencies. The examination for concretions must be very thorough, because in most instances they are pure cholesterin calculi, which so easily disintegrate.

Remarks. — Gentlemen, we have endeavored to present you a comprehensive review of cholelithiasis as we have observed it in infancy and early childhood, and we have also endeavored to prove that cholelithiasis is a not uncommon cause of disease in children. Perspicuity has sometimes caused the lines to be drawn with a little more shading than they are met with in nature, and, after all, this must be regarded as only a presentation of typical symptoms without the perplexities of diagnosis encountered at the bedside. Quick objective perception of the pathological condition is so important in surgical diagnosis, and particularly in its application to pædiatric practice, that our excuse for absorbing your time to such length this evening with matters pertaining to diagnostic technology must be that, since cholelithiasis in infancy and childhood is generally considered so extremely rare, and even by one of the latest authorities,[9] there is evident necessity for calling attention to those means by which gall stones when causing trouble may be detected with reasonable certainty during this period of life.

MULTIPLE NEURITIS.[1]

By STERLING RUFFIN, M.D.,

PROFESSOR OF MEDICAL JURISPRUDENCE AND DEMONSTRATOR OF ANATOMY, MEDICAL DEPARTMENT OF THE COLUMBIAN UNIVERSITY; ONE OF THE ATTENDING PHYSICIANS TO THE HOME FOR INCURABLES, WASHINGTON, D. C.

NEURITIS, or nerve inflammation, occurs in two forms, viz.: (1) Inflammation of a single nerve or group of nerves, and (2) a general inflammation of all or many of the peripheral nerves. The latter is known as multiple neuritis, and is the subject of this paper.

Multiple neuritis is also known as polyneuritis, peripheral neuritis, and disseminated neuritis. It is only during the last few years that it has been recognized as a distinct disease, although James Jackson, of Boston, described alcoholic paralysis in 1822. Dumenil first described peripheral neuritis, as such, in 1864. Joffroy made valuable observations in 1879, which were confirmed by Leyden in the following year; and in 1881 Grainger Stewart wrote fully on the subject. It is only since the comparatively recent writings of Stewart that general attention has been directed to the disease in this country. It is conveniently divided, after the manner of James Ross, into five classes—the idiopathic; the toxic; the dyscrasic; the sensory, vasomotor, and trophic; and the irritative.

The frequency with which the disease is encountered and the favorable prognosis, as compared with the spinal diseases, acute and chronic, with which it may be confounded, make it at once of interest and importance to those of us who are brought into contact with general diseases.

Generally speaking, its etiology is well known, and the cause may be summed up as the presence in the blood of a nerve poison, of varying composition, developed in the body or introduced from without. The poisons developed in the body are either those of infectious diseases, especially of diphtheria, but also, though less frequently, of scarlet fever, typhus and typhoid fevers, measles, grippe, tuberculosis, smallpox, pneumonia, malarial fever, leprosy, syphilis, and rheumatism; or of the dyscrasiæ due to chlorosis, marasmus, cancer, and other cachectic diseases, or vascular degeneration. Pre-eminent among the poisons which have their source from outside are alcohol and lead, but various other poisons, metallic and otherwise—among which are arsenic, mercury, phosphorus, silver, carbon monoxide, bisulphide of carbon, and aniline—are frequent causes. Cold is a frequent cause, and it is probable that it acts by producing some poison, the nature of which is unknown, developed as a result of exposure.

The essential symptoms of multiple neuritis are motor, sensory, and trophic disturbances; but inasmuch as any or all of these may be due to various other nervous diseases, of a more or less serious character, it becomes a matter of great importance to determine accurately when they are and when they are not indicative of a peripheral nerve inflammation.

In the idiopathic variety the onset is sudden, resembling the invasion of an acute infectious disease. Frequently it is ushered in with a chill, followed by pain in the back and limbs, with a rise of temperature to 103° or 104° F., together with headache, loss of appetite, and general malaise. The sensory symptoms are tingling and formication in the hands and feet and general muscular aching and tenderness. There is, in some cases, soreness throughout the entire limbs, the muscles and nerves being equally sensitive, so that it is not easy distinctly to define the nerve trunks themselves. Loss of muscular power soon follows, beginning usually in the flexors of the feet and extending upward, as in Landry's paralysis. In severe cases the paralysis may be general in a few days, extending to the trunk muscles and muscles of respiration. The paralyzed muscles atrophy rapidly and become soft and flabby. The deep reflexes are lost early, while those of the skin vary, remaining intact in some cases and being lost in others. The electrical reactions of the muscles, in this type of the disease, undergo no change except in severe cases and after the disease has lasted for some time.

The course of the affection varies with the extent and intensity of the attack; a case may terminate fatally within a week or may last five or six weeks before any material change takes place. The paralysis may last for months or years, with atrophy and contraction of the muscles, but with gradual restoration of muscular power.

Alcoholic neuritis is by far the most frequent form of neuritis, and it differs in material particulars from the idiopathic variety just described. As its name suggests, its cause is the constant and excessive use of alcohol in one form or another. It is most frequent in whiskey drinkers, but occurs also in beer drinkers and those who are steady drinkers of gin and brandy. Women are attacked more frequently than men, the ratio being about three to one. This circumstance is due either to the fact that women who once become addicted to alcohol are apt to "tipple" more steadily than men, or possibly, as suggested by Gowers, to the fact that there is a difference in the constitution of the nervous systems of the two sexes, which renders the peripheral nerves of the female more susceptible to alcoholic poison. The appearance of the disease may be the first revelation to the physician or family of the habit of secret drinking. The earlier symptoms are sensory, consisting of pain in the extremities, with sensations of pins and needles and formication. Often the tactile sense is blunted; often there is marked hyperæsthesia. The onset is usually gradual, and may be preceded for weeks or months by neuralgic pains and tingling in the feet and hands. The paralytic symptoms also set in, as a rule, gradually, the feet and legs being first involved, and subsequently the hands and forearms. On the contrary, the disease may be acute at its beginning, as evidenced by fever ranging from 101° to 103° F., and by a rapid pulse, varying from 100 to 150 a minute; and the elevated temperature and accelerated heart beat may persist for four or five weeks. There is a characteristic and striking tendency to the involvement of special homologous nerves, namely, in the leg, the peroneal, supplying the flexors of the ankle and extensors of the toes; and in the arm, the posterior interosseous, supplying the extensors of the wrists and fingers—giving rise, respectively, to "footdrop" and "wristdrop." Footdrop is as typical a symptom of alcoholic neuritis as is wristdrop of lead palsy. The paralyzed foot flexors give to the patient a distinctive walk, known as the steppage gait; the foot is thrown forcibly forward, the toe being lifted high in the air so as to prevent tripping. The gait is a clumsy, awkward one, producing the appearance of a constant effort to step over obstacles in the way. In some of the more acute cases the hyperæsthesia of the extremities, especially of the soles of the feet, is so great that the slightest touch is exquisitely painful, and the tenderness over the muscles and inflamed nerves is excessive. The paralysis may extend so rapidly as to become complete within two weeks, and the disease may terminate fatally in a few days; but in most cases the progress is slow, and after an interval of a few weeks or months recovery begins. The tendon reflexes are lost early, but in many cases the skin reflexes remain unchanged; occasionally the knee jerk is preserved, and two cases were reported in the *British Medical Journal* of February 28, 1893,

[1] Read before the Clinico-Pathological Society of Washington, D. C., January 18, 1898.

by Maude and Clarke, in which the knee jerk was exaggerated. In the cases in which this tendon reflex is preserved, the quadriceps extensor has escaped paralysis. The paralyzed muscles become soft and flabby and atrophy with great rapidity, and contractures producing the claw hand and extreme extension of the foot, from shortening of the tendo Achillis, are of frequent occurrence. Usually these deformities subside as recovery progresses, but occasionally they are permanent. The normal reactions of the nerves and muscles to electrical currents are changed. In mild cases the atrophy may be slight and the altered electrical reaction only quantitative, but in severe types the wasting of the muscles is pronounced, and there is "reaction of degeneration." Normally both nerve and muscle respond to galvanic or faradic stimulation; with galvanism the strongest contraction is produced by the negative pole at the moment of closing the circuit. When degeneration of the nerve fibres has occurred, there are a loss of faradic irritability by both the nerves and muscles, and a loss of galvanic irritability by the nerves; the muscles respond, however, to galvanism, and to a weaker current even than normally, but not with the normal quick and sharp contraction. They contract with a slow, peristaltic movement, and may show greater irritability to the positive than to the negative pole. In some cases inco-ordination is a prominent symptom, and when it is pronounced constitutes a special type of the disease, known as ataxic neuritis. In some cases also there are a swaying of the body and an inability to stand with the eyes closed.

Trophic cutaneous changes are not frequent, but occasionally the skin of the extremities becomes red, glossy, and possibly œdematous, and the nails may be roughened.

In most cases, as would be expected from the patient's intemperate habits, there is a complication of some form of kidney disease.

Brain symptoms also occur in most cases. In some instances they take the form of hallucinations of various kinds; in others there are delusions of grandeur; while in others still they consist merely of confusion as to environments. Depression of spirits is unusual; impairment of memory, especially for recent events, and insomnia are almost constant.

Before passing to a further consideration of the subject, it is interesting to note here that a case of alcoholic neuritis may present many of the symptoms of locomotor ataxia, with which it is more than likely, from a superficial examination, to be confounded, although the one tends with proper treatment to recovery, while the other is hopelessly incurable and tends to ultimate death. The symptoms which the two diseases may have in common are impairment of sensation, loss of patellar reflex, swaying of the body when blindfolded, or Romberg's symptom, and inco-ordination. These symptoms, though due entirely to an alcoholic neuritis, might easily be mistaken for those indicative of a sclerosis of the posterior columns. The duration of a mild attack of alcoholic neuritis is from four to six weeks, but in severe cases which recover the symptoms may persist for as long a time as two years, and restoration of muscular power may not be complete for several additional years. Generally power is restored first to those muscles affected last and least.

The history of alcoholism, with marked sensory disturbances and extensor paralysis, together with the peculiar mental disorder, makes the diagnosis in most cases easy. In those cases, however, in which the addiction to alcohol is unsuspected, an error of diagnosis is quite possible.

The prognosis is more favorable than in any other form of multiple neuritis. Naturally it depends to a great extent upon the patient's age, previous habits, and general health. If there is extensive kidney, liver, or stomach involvement, of alcoholic origin, the outlook is unfavorable. Death may occur within a few days from paralysis of the diaphragm or other respiratory muscles, or from heart failure due to involvement of the pneumogastrics; while in other cases a fatal termination may result from acute pulmonary complications, especially pneumonia, to which alcoholic *habitues* are so liable.

Neuritis from carbonic oxide is not very frequent. In this country it usually results from the inhalation of illuminating-gas. It may result, however, from being in a room in which charcoal or coal fire is burning, in which there is an insufficent supply of oxygen. Its symptoms are numbness, impairment of tactile sensibility, pain in the extremities, and paralyses, irregular and variable in their distribution, differing in the latter particular from other forms of neuritis. Frequent accompaniments are redness of the skin, œdema, and herpetic eruptions over the course of the nerve trunks.

Multiple neuritis may also arise from other forms of diffusible poisons, such as aniline and dinitro-benzin, but the symptoms do not differ essentially from those just referred to.

Aside from alcohol the most frequent cause of peripheral neuritis is perhaps lead poisoning, the most striking feature of which is paralysis of the wrist extensors, a symptom which should suggest lead palsy at first sight. It is a curious fact that the supinator longus muscle, the nerve supply of which is derived from the same source as that of the paralyzed extensors, is usually not affected. Sensory symptoms are either entirely wanting or but slight. The pain, if any, is dull and deep seated; the tendon reflexes are lost; frequently there is obstinate constipation, and in some cases there is considerable tremor. This form of neuritis occurs most frequently among painters, plumbers, and others whose occupations bring them into contact with the metal or its compounds. Accidental sources are drinking-water which has passed through lead pipes and the use of cosmetics containing lead. The presence of a blue line upon the gums, extreme anæmia, and a history of colic are usually sufficient to suggest the nature and variety of the disease.

Arsenical neuritis presents the same symptoms as the neuritis of lead, except that in the former the lower extremities are more frequently involved and the sensory symptoms more prominent; while mercurial neuritis usually affects the lower extremities alone. The arsenical form results from the absorption of arsenic in various ways. It may have been taken in a single dose, with suicidal intent, or have been administered with the food with homicidal intent; sometimes it follows the medicinal administration of the drug. An instructive case was reported by Putnam in the *Boston Medical and Surgical Journal* for September, 1888, which resulted from the administration of Fowler's solution in five-drop doses for a period of only six weeks. Arsenic in this case was recovered from the urine; and this reminds us that the urine should be examined for arsenic in all doubtful cases. Other sources of arsenic are wall papers and dyes. Mercurial neuritis occurs occasionally in syphilitic subjects who are being treated with hypodermic injections of mercury. It occurs more frequently, however, among workers in the metal, especially if they are accustomed to inhale mercurial vapors. In the latter class of cases there has usually been a prolonged exposure, but it is possible for the disease to develop although the exposure has been brief. Dr. Christison reported the case of two barometer makers who slept one night in a room containing a pot of mercury upon a stove. One of the men was severely salivated, and the other was affected with a shaking palsy which lasted all his life.

Of the infectious diseases, the poison of diphtheria is most liable to cause peripheral neuritis. The paralysis commonly begins in the palate; the voice changes and there is difficulty of deglutition, with a tendency to the regurgitation of liquids through the nose. Frequently the paralysis extends to the muscles of the eyes, and the ciliary muscle is specially liable to involvement, giving rise to loss of power of accommodation and impaired vision. The arms are affected next in frequency, and lastly the legs. Sensation is disturbed in about fifty per cent. of the cases. Diphtheritic paralyses tend to recovery. The dangers are involvement of the nerves supplying the diaphragm and other muscles of respiration, and the vagus, supplying the heart, either of which occurrences is a signal of great danger. The paralysis is almost invariably bilateral.

The diagnosis is usually made without difficulty. The fact of a paralysis developing in a child who has had diphtheria is usually sufficient to establish the nature of the disease. The use of the antitoxin does not seem to have diminished the frequency of diphtheritic paralysis.

Peripheral neuritis is liable to occur in diabetic patients, and its cause under such circumstances is believed to be toxic materials resulting from or causing the glycosuria.

There is a form of paralysis occurring in malarial districts, especially in Jamaica, believed to be a multiple neuritis due to malarial poisoning. In this form of the disease there are much pain in the extremities and great muscular atrophy. Skin eruptions are frequent, and the pigment of the skin is increased.

Chief among the other infectious diseases which are liable to be complicated or followed by a general neuritis are typhoid fever, rheumatism, syphilis, tuberculosis, and leprosy. In leprous neuritis the most conspicuous features are said to be anæsthesia, muscular weakness, and atrophy.

Peripheral neuritis in the aged has been described under the name of senile multiple neuritis, and is believed to be due to arterio-sclerosis.

The only remaining form of the disease to be discussed is the endemic neuritis, beriberi. This is an infectious and contagious form of neuritis, met with in epidemics in Japan, China, India, Ceylon, the Philippine Islands, Newfoundland, and the coast of Brazil, and is due doubtless to a specific micro-organism, which, however, has not yet been positively isolated. Among the predisposing causes, diet appears to have a very close etiological relation. Many cases have been reported among the fishermen on the banks of Newfoundland, in which the disease seemed to have developed in consequence of insufficient and unsuitable food. Food lacking in albumin has been considered to be a cause, and epidemics in China and Japan have been ascribed to the fact that in those countries rice is eaten largely to the exclusion of other articles. Takaki, a Japanese physician, states that he has reduced the number of cases in the Japanese marine service to an enormous extent simply by adopting a food regimen in which beef, pork, eggs, etc., are given in addition to rice. In 1884, he reports, there were seven hundred and thirteen cases; in 1889, none at all. Cases have been reported as occurring on vessels laden with sugar, in which the predisposing cause was believed to be the carbonic-acid gas and toxic matters arising from fermentation in the holds of the ships. The symptoms are much like those of other forms of multiple neuritis, except that there is a greater liability to the involvement of the nerves of the heart, with resulting tendency to œdema and effusions into the serous cavities. Mild attacks develop gradually, and under proper treatment are recovered from in a few days. In severe cases the outlook is best for those in which there is little œdema. The atrophy may be extreme, and the pain and paræsthesia are said to be almost intolerable.

Intestinal parasites are also believed to be a predisposing cause.

The morbid anatomy of an inflamed nerve is quite well known. In recent cases the nerve appears to the naked eye red and swollen, and its blood-vessels are distended and plainly visible. Microscopically leucocytes can be seen surrounding the vessels and infiltrating the sheaths of the nerves, and frequently small extravasations of blood can be recognized. If these changes are confined to the nerve sheath, the condition is called a perineuritis; if they extend into the tissue between the bundles of nerve fibres, it is known as an interstitial neuritis. In interstitial neuritis leucocytes are also found in the septa between the nerve bundles. When the inflammation begins in the nerve fibres, it is called a parenchymatous neuritis. In parenchymatous neuritis the changes in the nerve fibres are the same as in degeneration; the medullary sheath is first swollen and then the myelin breaks up into segments, which later become divided into small fragments. The masses filling the nerve tube become cloudy and granular, and the axis cylinder is interrupted wherever the myelin is divided. The nuclei of the sheaths are increased in number. Later the axis cylinder disappears entirely, the sheaths become empty and shrivel, and are replaced by connective tissue and fat. This process goes on often to the complete destruction of most of the fibres in the nerve, a few fibres only remaining unchanged. In multiple neuritis the inflammation is chiefly of the parenchymatous type, and involves the peripheral branches throughout. The nerve trunks proper are usually but slightly affected or not affected at all, although they may be tender to the touch. After a time regeneration begins, and this occurs either from the development of new axis cylinders and sheaths from the nuclei in the old sheaths, or, according to Ranvier, from the growth of axis cylinders from the undegenerated part of the old nerve fibre.

The changes which occur in the atrophied muscles are, macroscopically, a reduction in bulk, and, microscopically, diminished size of the fibres, with probable loss of striation and granular degeneration, and, in bad cases, fatty degeneration.

An important and interesting fact to be considered in connection with the morbid anatomy is that in some cases there is an involvement of the spinal cord. It was long ago discovered and demonstrated by Waller that when a nerve fibre is cut the peripheral portion —that is, the part separated from its trophic centre— degenerates. But it has been found by physiologists in recent years that the part of the nerve still connected with its trophic centre may also degenerate, which degeneration is known as "retrograde degeneration," in contradistinction to Wallerian degeneration. This type of degeneration may extend to and involve the spinal cord. It may involve different portions of the cord—its anterior, lateral, or posterior columns, or the cells of the gray matter—but affection of the posterior columns and posterior nerve roots is most frequent. Usually only a portion of the fibres in the affected area is diseased, many healthy fibres remaining among those which have degenerated.

The diseases with which a multiple neuritis is liable to be confounded are acute ascending paralysis of Landry, diffuse myelitis and spinal meningitis, anterior poliomyelitis, and locomotor ataxia.

Landry's paralysis begins in the lower extremities, next attacks the trunk, then the upper extremities, and finally extends to the medulla. It is usually wholly motor, sensory symptoms being entirely lacking or very slight; the bladder and rectum are not affected; muscular atrophy is either absent or occurs only in

those cases which have an unusually long duration; and there is unaltered electrical reaction of the nerve and muscle. The disease is a very fatal one, and its course is rapid, many cases terminating fatally within a week or less. There is considerable doubt as to its exact nature. The tendency is to regard it, in fact, as a special type of peripheral neuritis rather than as a disease of the cord.

In diffuse myelitis and spinal meningitis the usually symmetrical distribution of the paralysis of multiple neuritis is lacking; the muscular atrophy is less, and there is less alteration of electrical reaction; the tendon reflexes are exaggerated, the bladder and rectum are frequently involved, "girdle" pains are common, and bedsores are frequent.

In anterior poliomyelitis the diagnostic features are the age of the patient, the rapid onset of the paralysis with partial disappearance after a few days, the irregular distribution of the paralysis, and the lack of sensory symptoms. Muscular atrophy and change in electrical reaction are the same as in neuritis.

The disease with which multiple neuritis is most apt to be confounded is locomotor ataxia. As already stated, the symptoms which may be common to both are impairment of sensation, loss of patellar reflex, Romberg's symptom, and inco-ordination. The progress of locomotor ataxia is slow; there is for a long time no loss of muscular power, although inco-ordination may be marked; the muscular tenderness of neuritis is absent; there is special tendency to involvement of the sphincters; "girdle" pain and a history of lightning pains in the limbs, very different from the pain of neuritis, are usual; optic-nerve atrophy is fairly constant; and altered pupillary reaction is almost invariable. The pupil contracts for accommodation, but is irresponsive to light (Argyll-Robertson pupil).

The prognosis in multiple neuritis is variable, depending largely upon the patient's general condition and power of resistance and our ability to determine and remove the cause. When, in addition to the paralysis of the extremities, the trunk muscles are also weakened, respiratory difficulties are to be expected and life is endangered. When the paralysis shows no tendency to extend—that is, when the disease reaches a stationary stage—the outlook improves. Paralysis of the diaphragm is a very unfavorable symptom. In cases in which the occurrence of bedsores or paralysis of the bladder points to involvement of the cord, the prognosis is always serious. In some cases, especially those due to alcohol, death may occur within a few days from pulmonary congestion or heart failure, due to involvement of the pneumogastrics. Patients who have sufficient vitality to live until nerve regeneration has begun, will generally recover. In young subjects recovery is the rule, and in cases of moderate severity the restoration of muscular power after a longer or shorter time is generally complete.

A knowledge of the cause and dangers of the disease will point the way to intelligent treatment. The chief indications are to remove the cause and eliminate the poison. When the cause is alcohol and there is reason to fear that its withdrawal will be attended by heart failure or serious nervous depression, the administration of strychnine, alone or combined with the carbonate of ammonium, digitalis, or strophanthus, will be found serviceable. When the cause is lead, arsenic, or mercury, their elimination can be hastened by frequent warm baths and the administration of iodide of potassium.

Absolute rest in bed should be insisted upon in all forms of the disease.

Symptomatic treatment is necessary in most cases for the relief of pain, which in many instances is urgent. For its relief, cannabis indica, acetanilid, phenacetin, antipyrin, ammonol, or morphine may be used. The use of the coal-tar products should be with extreme caution; frequently they are entirely contra-indicated by a weak heart. For my own part, I much prefer to rely upon morphine given hypodermically in such quantities as may be required, to the exclusion of other analgesic drugs. It is stimulating, is reasonably uniform and sure in its action, and there need be no fear, if it is used judiciously, of the morphine habit. It should be withdrawn gradually as the pain subsides. The pain usually disappears many weeks before the patient is able to be out and around sufficiently to procure the drug, even though there should be a temporary craving for it. Hot fomentations and poultices applied over the inflamed nerves and painful muscles will often make the use of other measures designed to relieve pain unnecessary. In alcoholic cases, when the entire withdrawal of alcohol is followed by serious depression, cocaine, in doses of one-eighth or one-fourth of a grain, is said to act well, not only as a stimulant, but also as an analgesic. Electricity in the form of the galvanic current passed continuously down the limbs will often effectively allay pain.

Another symptom which may require treatment is insomnia, for which the bromides, chloral, or hyoscine may be used. The hydrobromate of hyoscine given hypodermically in doses of one-one-hundredth of a grain is usually effective, especially in those cases in which there are symptoms of mental derangement.

Massage is of great importance, as in most other atrophic muscular conditions. It may be used by a skilful operator from the beginning of the attack. During the early stage the movements should be made with the greatest possible gentleness, but later on when the acute symptoms are subsiding deep massage may be used with great advantage.

During the acute period of the disease galvanism is indicated, though only for the purpose of relieving pain. Later the faradic current is useful to exercise the muscles artificially and prevent their wasting.

Contractures should be prevented as far as possible by giving proper attention to the patient's posture and using such pads or other mechanical devices as may be required.

During convalescence iodide of potassium (if it is borne well) and tonics, especially arsenic (unless the disease is due to arsenical poisoning), iron, strychnine, and cod-liver oil, are serviceable.

During the acute stage the diet should be light; subsequently it should be generous, but always of an easily digestible and nutritious character.

I have had under my care three cases of multiple neuritis, the main features of which I herewith report:

Case I.—December 16, 1894, I was called to M. W——, white, male, aged eight years, whom I found to be suffering with a moderately severe attack of diphtheria. The membrane was on either tonsil and in the pharynx. The course of the disease proper was uneventful. The child never seemed to be very ill, and at the end of twelve or fourteen days was up and around the house, apparently as well as ever, except that its strength had not been entirely restored and it was a trifle anæmic. An iron tonic was prescribed and the case dismissed.

January 5, 1895, I was again called to the child, whose mother told me that it had had some difficulty in swallowing and that she had noticed a change in the character of its voice. Its palate was then paralyzed and from that time on for several days the paralysis was progressive, successively attacking the arms, some of the trunk muscles, and the legs. Deglutition became very difficult. The patellar reflex on either side was abolished. There was slight muscular atrophy of all of the extremities, most pronounced in the legs. The sensory symptoms consisted of pain

and numbness in the extremities. For two months the child was entirely unable to walk, and it was not until several months later that the muscular strength was entirely recovered. Recovery was eventually complete.

Case II.—June 14, 1896, I was consulted by Miss M——, white, aged forty-one, whom I had attended at various times during the preceding three years. She complained of numbness in the soles of the feet and of a tendency to stagger. On the preceding day she had stumbled and fallen in the street. Upon examination I found that the general sensation of the plantar surfaces of her feet was impaired, that the patellar reflex was diminished on either side, and that her gait was more or less ataxic. I did not suspect the existence of alcoholic poisoning at the time, although I have wondered, in the light of subsequent events, that her general appearance and increased rotundity had not suggested an addiction to alcohol. A week later I saw her again. In the mean while the impairment of sensation had extended half way or more to the knees, she complained of great pain and persistent numbness in her feet, the ataxia had become more pronounced, and the steppage gait, so characteristic of alcoholic neuritis, was unmistakably developing. After a few days the footdrop was fully developed, the feet became œdematous and purplish, the patellar reflex was entirely abolished, the electrical reaction was altered, the muscles became flabby and began to waste, and there was noticeable mental confusion. The extensors of the hands were involved, but to a minor degree, and the wristdrop was not complete. The patient would not for a long time admit her addiction to alcohol, although she subsequently did so, confessing that she had begun to drink whiskey seven years before and had taken it daily since that time, in gradually increasing amounts, to the date of the attack. She stated that she did most of her drinking after she had gone to her room at night, and that it had been her custom for a long time to go to bed comfortably intoxicated. She would not tell me the amount of her daily consumption. This patient remained in bed for four months, and for four months longer she was unable to walk. There was, in spite of the greatest care, some contraction of the tendo Achillis on either side. Massage and faradism were used persistently after the acute stage had passed, and apparently with good results. Twelve months after the commencement of the attack the patient walked comparatively well and the firmness and size of the paralyzed and atrophied muscles had been nearly regained. She is now quite well. The only alarming symptom during her illness was that during the earlier portion of it her heart was persistently weak and excessively rapid, the pulse at some times reaching 160 a minute. A gratifying feature of this case is that thus far the patient has been cured seemingly of the alcohol habit.

Case III.—J. V——, white, male, aged thirty-nine, a saloon keeper; first seen, September 1, 1897. History: Accustomed to whiskey and beer in large quantities for past ten years; five or six drinks usually before breakfast; amount of whiskey consumed daily at present, about one quart; general health good; had had no serious illness; during past three weeks had felt numbness and burning pain in feet and weakness in legs, noticed especially in going up and down stairs; had fallen once when descending the steps.

Upon examination tactile sensation of soles of feet impaired, muscular strength of legs reduced, patellar reflex diminished. From this time on paralysis developed comparatively rapidly; the extensors of the hand soon became involved, and in two weeks the wristdrop and footdrop were complete and the patellar reflex was abolished entirely: the trunk muscles were also weak; pain in the extremities and back at times was very severe; the patient was unable to turn in bed on account of great pain and weakness. Marked atrophy of paralyzed muscles. Electrical reaction very much altered. Mental confusion; does not realize that he is at home; believes his toes have broken off. No rectal or vesical symptoms. Patient in bed from September 4th to December 14th, at which latter date acute symptoms had sufficiently subsided to allow him to be lifted to a chair for a portion of the day.

Treatment: Nitrate of strychnine as substitute for alcohol; hot applications to limbs, and morphine hypodermically as required to control pain; daily application of faradic current and massage on alternate days during the two weeks preceding this report.

Wristdrop is improving; most of muscles of forearm respond to current; footdrop slightly improved, but still pronounced; mental confusion has disappeared; feet purple and slightly œdematous; small vesicle on extremity of great toe and adjoining toe of right foot. Heart's action regular and its strength good. Urine normal. Patient apparently gaining weight. Nitrate of strychnine has been discontinued, and elixir of iron, quinine, and strychnine ordered instead. No evidence of involvement of cord. Outlook good.

THE OBSCURE CASES OF GALL-BLADDER DISEASE.[1]

By EDWARD S. STEVENS, M.D.,
LEBANON, OHIO.

The enemy in ambush is the enemy to be feared. The unseen danger is the grave danger. Can we but know what emergencies to expect with certain conditions, we may prepare to meet them. Among the diseases with which the physician and the surgeon find themselves called upon to cope, and which have these characteristics of uncertainty, are those of the gall bladder with symptoms so obscure that their recognition is long a matter of great doubt, and the treatment of which consequently is equally unsatisfactory to physician and patient.

It is not a difficult matter to make a diagnosis of gall-stone colic when pain in the proper locality is so severe and cutting that the subject doubles himself into a bow knot, or gets down upon the floor and claws at the carpet; nor is it to be wondered at if one with little experience in medicine quickly arrives at the conclusion that there is an obstruction to the proper flow of bile if there are extreme jaundice, stools of the color of blue clay or putty, and very dark urine.

But these decided symptoms occur in the exceptional cases. The great majority of cases of gall-bladder disease are not recognized from such signs; many are not recognized at all, and the question is continually asked, "What is the matter with the American stomach?" when there is nothing at all primarily the matter with the poor old American stomach; and our offices are flooded with literature and samples of various digestive ferments warranted to cure just these very troubles that do not yield to the remedies when employed, for the salivary glands, the stomach, and the pancreas have already supplied all that is necessary in that line.

One instinctively feels that those cases of disease accompanied by such severe symptoms as colic and cholæmia are the graver cases. Yet when one thinks of it, these are but the symptoms which show us that nature is making an effort to free the delicately made gall bladder of an incubus of perhaps many years' standing, and that by a natural channel. They are grave cases, yet perhaps after a little period of anxiety

[1] Read before the Ohio State Medical Society May 5, 1898.

the stone may pass, the symptoms disappear, and possibly the disease be at an end.

What of the case before such symptoms come on? Is there not much more reason for anxiety when we consider our uncertainty as to the exact condition present, and whether, if there be calculi present, they may not ulcerate into the pelvis of the kidney, the portal vein, or the peritoneal cavity, or be found in an abscess of the liver, and that without giving rise to notable symptoms until the mischief is accomplished? And all of these conditions, and others, have been found after a variable history of mild gall-bladder disease.

In many of these cases we can in the first place merely be suspicious of the existence of gall-bladder disease. When one applies for relief from trouble with the stomach and gives a history of having applied for relief in vain to many well-qualified physicians, we may suspect that there is some condition present apart from the stomach. If the supposed signs of indigestion are independent of the taking of food into the stomach, our suspicion is strengthened. But this is not sufficient to establish a diagnosis of gall-bladder disease. The suspicion of it being aroused, months may elapse before anything is noticed, more than simple distress in the stomach with eructations of gas. Stones may be present and yet cause no pain, or catarrh of the gall bladder of low grade may exist without either pain, tenderness on pressure, or a perceptible tumor being noticed. If one does not hastily jump at a conclusion, he will sooner or later discover other signs of the suspected trouble. There may be a slight sallowness of the skin. If it is from bile, there will be a reaction in the urine upon the proper test, although the colors may be quite faint. There may be periodical passages from the bowels of strings of mucus, occasionally of blood also.

Just as certain mental emotions may cause at times the involuntary evacuation of the rectum or urinary bladder, so they may give rise to an effort on the part of the gall bladder to expel its contents. This may be more or less painful, or perhaps produce symptoms of distress so slight that it is not considered important enough to refer to a physician. I have seen this slight distress follow worry over business affairs and a lawsuit. In one such case the diagnosis was confirmed by the passage of a calculus from the bowels after a sharp attack of hepatic colic. In a second case prolonged and severe distress was caused by deep grief over the death of a child at one time, and at other times excitement produced a like effect. In another case hypochondriac distress was subsequent to a prolonged fit of laughter. The diagnosis, strengthened by other signs, was confirmed in this case by cholecystotomy.

Among the most interesting symptoms dependent upon the existence of gall-bladder disease with which I have met are certain reflex symptoms. In considering them one should bear in mind the extensive distribution of the branches of the pneumogastric nerve and the sympathetic. Among the most common of the reflex disturbances is palpitation of the heart. Another, which I have twice observed, is pain in the urinary bladder.

The following references to disturbances of the respiratory apparatus seem to me to be of some interest. I have never seen any mention of similar symptoms being apparently caused by irritation from biliary calculi or other disease of the gall bladder.

I. A lady, sixty-six years of age, applied to me for relief from pulmonary disease. There is a history of consumption in the family. She complains of shortness of breath, severe cough, and profuse expectoration. There is a history of "liver and stomach trouble," extending over a period of thirty years. She speaks of a constriction about her body, as if by a cord. Her pulmonary disease engaged my attention, and seemed sufficient to account for all of her symptoms. Some months after I took charge of her case my attention was directed to a tumor in the right side, which seemed to me to be a distended gall bladder, and not long afterward signs of obstruction were noticed—light colored stools, dark colored urine containing bile, and slight jaundice. It was from this time on that the patient and her family as well as the physician noticed that the distress in breathing always came on and her cough was more severe when the gall bladder became distended, or when there was pain or distress in the epigastrium or right hypochondrium.

II. A lady, about forty years of age, seemed to have obstinate laryngeal trouble. She was subject to violent spasmodic coughing-spells, frequently followed by aphonia. Examination of the larynx revealed nothing to account for these symptoms or for the great pain she experienced in her neck. Occasionally one or more of the cervical muscles would cramp, producing great pain. She complained of pain under the ribs on the right side. A guarded diagnosis was made of gall-bladder disease probably due to gall stones, and other signs were looked for. She had what seemed to be neuralgic pains in the chest and neck and an intermitting fever, the fever always preceded by a chill and coming on at the same hour daily. These were at first accounted for by the fact that she had been living in a malarial district. Very slight jaundice was observed several times, and repeated examinations of the urine gave at times the reaction for bile and at times none. Operation was advised and accepted. A few days previous to the operation she experienced one of her spasmodic coughing-attacks. This was relieved by full doses of morphine hypodermatically. A slight cough persisted until the day of the operation and was accompanied by aphonia. A large number of small calculi were removed from the gall bladder. When consciousness was restored, the patient's voice was clear and her cough was gone.

In a large number of the obscure cases of gall-bladder disease there will always be more or less doubt as to whether the gall bladder and ducts are diseased at all. Moreover, with a reasonable degree of certainty as to the location of the disease, there will always be more or less doubt as to the character of the disease; for, be it remembered, there are other forms of disease which produce gall-bladder disturbance besides gall stones and the inflammatory affections. In such cases, the symptoms not yielding to treatment, and being essentially chronic, it is eminently proper to advise an exploratory operation for the purpose of making certain the diagnosis. This may be advised, in the first place, because in the hands of one who is skilled in this work the danger is almost *nil*. In the second place, the propriety of such advice may not be questioned, because the exploration is the first step to be taken in a radical gall-bladder operation, and most of the chronic gall-bladder diseases require local treatment rather than medicinal, if a permanent cure is to be effected. Even though an incurable, a malignant disease be discovered upon opening the abdomen, it is a matter of great satisfaction to know positively what condition is present—what not to treat. It has happened, too, in numbers of cases that relief followed the simple exploration, although the abdomen was closed with the knowledge that malignant disease of or near the gall bladder was responsible for the symptoms for which relief was sought.

Uric Acid.—It is now very generally conceded that uric acid is formed in the tissues and excreted by the tissues.—Osler.

CRESCENTIC ASTIGMATISM.

By NORBURNE R. JENKINS, M.D.,
KNOXVILLE, TENN.

Upon a minute and careful ophthalmometric inspection of the cornea we shall find to exist in a very small percentage of eyes a curvilinear[1] astigmatic axis, deviating one to thirty degrees from an axial tangent, which is ordinarily present in astigmatism.

As an example we will give an exaggerated case: We will suppose the primary axial point to be 90°. Upon describing a quarter circle with the indicators of the ophthalmometer we find that the hairlines of the mires are not in apposition and become so only by a backward rotation of 30°, thus indicating the secondary axial point to be 60°.

To simplify matters, we furnish the following diagrams: Figure *a* represents the perfect apposition of

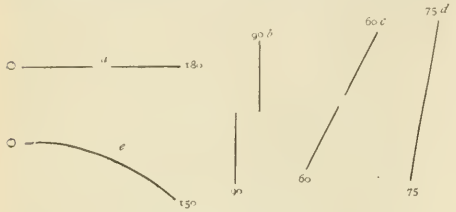

Diagram (Crescentic Astigmatism).

the hairlines of the mires in the first position, and indicates the primary axial point to be 90° (assuming the astigmatism to be W. R.).

Figure *b* represents the hairlines of the mires in the second position and shows deviation.

Figure *c* represents the hairlines of the mires, showing the lines to be in apposition, and indicates the secondary axis to be 60°.

Figure *d* represents the proper axis, 75°, for a correcting-cylinder, which is a compromise between 90° as shown in *b*, and 60° as shown in *c*.

Figure *e* represents the curve of the astigmatic axis as it hypothetically exists in the cornea.

What has been said above has no reference at all to corneal astigmatism resulting from pathological changes.

[1] The liberty is taken of adding the qualification "curvilinear" to the word "axis."

Progress of Medical Science.

Treatment of Carbuncle.—Dr. S. N. Rosenbaum recommends the following method: Fold a piece of aseptic gauze until it forms a thickness of six to eight layers, the surface area to be somewhat larger than the carbuncle to be covered. The gauze is first thoroughly saturated with Thiersch's solution, then covered with a layer of a ten-per-cent. ointment of ichthyol, and then applied to the carbuncle. A piece of rubber protective large enough to overlap the gauze is now placed on the same to keep in the moisture. A layer of cotton is placed on the protective, and then the bandage is applied and allowed to stay on for two days. When the patient returns to be rebandaged and to have the dressings renewed, the cores are found to have separated from their respective walls, and at the next redressing, which is again in two days, they are found entirely separated, and can be easily and painlessly removed. At the next visit granulation has passed the primary stage, and healing quickly results, leaving an almost invisible scar. The only constitutional treatment which has been found necessary is to give cathartics, like fluid extract of cascara sagrada or castor oil, and in individual anæmic or cachectic cases compound syrup of the hypophosphites. The advantages claimed for this method are: 1, painlessness (a great factor with many patients); 2, quickness of healing, more so than with other methods; and 3, no scar or cicatrix remaining—important when carbuncles are in visible parts.—*New York Medical Journal*, June 11, 1898.

Exclusion of the Chemical Rays in Small-Pox.—Dr. Herman Backman reports sixty-two cases of smallpox treated by him at Wibourg after Finsen's method of excluding the violet rays by means of red curtains to the windows (*Finska Läkaresällskapets Handlingar*, May, 1898). Of these patients, three adults and four children under two years of age died. In the other cases the results of treatment were excellent. The stage of suppuration was of short duration, and there was no pitting. The mean number of days in hospital was 19.5, which is below the average. The author has also treated other acute exanthemata, such as scarlet fever and measles, in the same way and with equally good results. As a protection against freckles, he recommends the wearing of a red veil when exposed to the sunlight in the spring and summer.

New Method of Sterilization.—A process for successfully avoiding any undesirable features or qualities imparted by the usual method of sterilization has been brought to the attention of the French Academy of Sciences by M. Duclaux, the eminent chemist; the principle thus explained consisting in subjecting the liquid thus to be sterilized to the desired temperature in a closed vessel, under high pressure and away from contact with air. The apparatus used for this purpose is about equally simple, the sterilizer consisting of a steel tube silvered within and surrounded by a steam or water jacket formed of a second cylinder of slightly larger dimensions, suitable connections and stopcocks being provided, as well as the thermometers and pressure gauges, and the mechanism so mounted as to be revolved by the turning of a crank. Some information on this matter, communicated by Professor Bilslik, is in point, namely, that water may be sterilized in five minutes by adding to it bromine, and that bromine may then be neutralized by adding ammonia. The river water of Berlin, it is stated, has been tested two hundred times, and, after being treated with bromine and ammonia, all germs of disease were destroyed, including those of typhoid and cholera. In thus sterilizing a gallon of water, there are first added three drops of a solution of one hundred parts water, twenty parts bromine, ten parts potassium bromide, there being added after five minutes three drops of a weak solution of ammonia.

The Therapeutic Use of Hot Air.—Dr. Mendelssohn (Berlin) says that the treatment of chronic arthritis is almost exclusively a question of temperature, and that the most efficacious method is the application of hot dry air, which allows a high temperature to be maintained for as long a time as may be required and does not produce any undesirable symptoms. Dr. Mendelssohn, following the example of English physicians, has made use of hot dry air, and has proved that temperature of from 120° to 140° C. (from 248° to 284° F.) could be borne by patients for several hours. The subjective sensations were not disagreeable, and no unfavorable consequences were produced on either the pulse or the temperature. The immediate local effect on the joints was at once very obvious, especially in chronic rheumatism, gout, and other affections of the joints. Sometimes after the first application of the hot air they became temporarily more movable, but of course to obtain a substantial improvement the treatment must be applied for a longer time.—*The Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 9, 1898.

RESTRICTIONS OF MEDICAL PRACTICE.

IN the current number of *The Arena* are two articles relating to the medical profession. The first, entitled "The Medical Trust," is contributed by Prof. T. A. Bland, and is an indictment of the action of the physicians in defending themselves by legislation from the encroachments of those commonly known as quacks. The homœopaths and eclectics are also severely criticised for having in their own defence joined hands with their professional brethren in many of the States. The composition in question is a somewhat slovenly performance, besides being decidedly vague and inconclusive; its effect, too, is considerably marred by the animus that pervades the article throughout. The arguments employed in the support of the contention that legislation in the interests of one class of physicians is in a high degree harmful will fail to convince any one who is tolerably well acquainted with the subject. The accuracy of some of the statements is, to say the least, open to grave doubt. For example, when we are told that Paracelsus was the founder of the old school, and that this "school" of medicine is based upon the theory of "*contraria contrariis curantur*," the English of which is that the way to cure one disease is to create another disease of a different sort, we are filled with amazement. In the first instance, although probably the records existing concerning Paracelsus cannot be wholly depended upon, yet the belief is general that, so far from the old school being founded on his teachings, on the contrary he was the most prominent figure among the mediæval charlatans. Secondly, Prof. Bland must allow that his translation of "*contraria contrariis curantur*" is rather too free and imaginative. However, these are points of but comparatively small importance. The pith and gist of the article lie in the fact that it is an endeavor to prejudice higher education in the minds of the general public. It is an attempt to throw dust in the eyes of the community at large, and to prove that education is a factor of small moment in the production of competent physicians. In support of this view the state of the country before the civil war—when there were no laws restricting medical practice—is cited, and the insinuation is made that such a condition of things is preferable to that prevailing now. Dr. William R. Fisher takes up the cudgels on behalf of the medical profession, and in a very able article exposes the fallacy of Prof. Bland's arguments and sharply scores him for his "stab-in-the-back" methods of fighting. In the course of his remarks Dr. Fisher says: "In considering Prof. Bland's paper the reader should keep clearly before him the main issue which the author sets out to establish—namely, the existence of a medical trust, which has been created since the termination of the civil war. All irrelevant matter should be put on one side and not taken into account. In this way the first half of the article can be promptly disposed of." Dr. Fisher then sketches in a clear way the happy conditions of affairs which existed before our civil war, when "medical practice was absolutely free." And he goes on to say: "The combination did not have its origin in the low and mercenary motives which Prof. Bland chooses to ascribe to it. When the medical profession was at its lowest grade, owing to the absence of proper legal restrictions, a resolute attempt on the part of a few to better the deplorable condition was met with hearty approval. Happily for the good name of our country and the welfare of our people, the true men and women of the medical profession have not been influenced by the motives which appear to actuate Prof. Bland. The movement for reform in medical education began at once to enlist the sympathy and support of high-minded physicians in all the so-called schools. Little by little the work has gone on. To further its advance old quarrels have been reconciled and opposing interests have been conciliated to a degree that at one time seemed to be unattainable. Men who a few years ago were wrangling among themselves about theoretical questions have agreed to set aside differences of opinion that they may join together in a practical effort to raise the standard of medical education to the high position which it holds in other civilized countries. This united action on the part of the physicians, irrespective of the schools, to elevate the dignity of their calling and to protect the public from half-educated doctors as well as from unprincipled quacks, Prof. Bland sees fit to call 'The Medical Trust.' He is at liberty to call it what it pleases him, but it will take more than a slurring epithet to stir up popular prejudice against legal restrictions which have been enacted in the interests of the people." The fact is pointed out that the restrictive medical laws relate alone to matters of education, and do not deal with particular theories of practice or systems of treatment. But Prof. Bland claims that "under the operations of the existing laws it has been declared a crime, punishable by fine and imprisonment, for a physio-medical physician to cure a patient with his non-poisonous vegetable remedies; for a disciple of Priessnitz or Father Kneipp to cure a sick person with water; for a vitapathist to heal the sick by the magnetic power that the Nazarene used so successfully in His day; or for the mental healer or Christian scientist to practise his system for the relief of human suffering." Referring to these remarks Dr. Fisher says: "This is a bold statement. It is the kernel of his article; all the rest is merely husk and padding. Upon this he relies to rouse up popular resentment and to prejudice legislators against the cause of the higher medical education. Here, again, with ambiguous phrase, yet showing plainly the animus which has prompted

him throughout his crafty attack, he seeks to mislead the unguarded reader into a pitfall of deception. This skilfully constructed paragraph is intended to convey to the popular mind the impression that legislative acts have been passed at the instigation of an intolerant, bigoted, and persecuting combination of medical men, to define what remedies may be used by physicians and to restrict them in their methods of practice." That such is not the case every physician knows full well, but the credulous public is apt to be led away by statements of a like nature, and therefore it is advisable that the facts should be placed before them in a clear manner. There can be no objection to Christian scientists, faith healers, or followers of Father Kneipp, pursuing their modes of treatment, provided that they comply with the conditions of the law. The laws restricting the practice of medicine were framed and passed just as much for the benefit of the people as for that of the physician, and we believe that when the truth of this is thoroughly understood it will also be as thoroughly appreciated. Thoreau has remarked that nothing more strikingly betrays the credulity of mankind than medicine; quackery is a thing universal and universally successful. In this case it becomes literally true that no imposition is too great for the credulity of men. There can be no doubt that to abolish the restrictions regulating the practice of medicine would be to open the door to impostors of every kind, and charlatanism would be once again rampant in the land. Happily so retrograde a step is not likely to be taken. On the contrary, it seems probable that in the future these restrictions will be more strictly enforced and more universal.

H. Carrington Bolton, writing in a late number of *Science*, on quackery in general and the methods of Mattei in particular, ends by saying: "All this would be very amusing were it not sad—sad to find that educated men can so degrade their knowledge of chemistry, physiology, and medicine; sad to think of the conceptions of these sciences formed by persons subject to the influence of these lewd impostors; sad to think of the suffering that ensues for lack of proper treatment; sad to think of the unscrupulous immorality of those willing to trifle with human life for selfish gain. One is inclined to cry with Massinger:

> " 'Out, you impostors,
> Quacks—salving, cheating mountebanks. Your skill
> Is to make sound men sick, and sick men ill.' "

THE VALUE AND LIMITATIONS OF EXAMINATIONS OF THE GASTRIC CONTENTS IN DISEASES OF THE STOMACH.

In an interesting article in the *National Medical Review* for February, 1898, Dr. Max Einhorn, of this city, treats of the value and limitations of examinations of the gastric contents. While a large number of practitioners seldom avail themselves of these examinations, there are some who exaggerate their importance. The golden mean lies, however, between these two. If these examinations are made in appropriate cases, they yield most fruitful results; if practised indiscriminately, they may often prove valueless.

The question now arises: When are examinations of the gastric contents necessary and when not? On the whole, Dr. Einhorn says, they may be omitted whenever we are able to arrive at a positive diagnosis without them, and in all acute conditions, the latter generally tending to amelioration in a short while. Further, they are not absolutely necessary in chronic conditions which are apparently improving under the established regimen, and in the majority of purely nervous affections of the stomach. In cases in which there is suspicion of an ulcer, the tube should be used with utmost care, and, if possible, should be replaced by the stomach bucket. In cases of ulcer with hemorrhage it is best to forego both the tube and the bucket. Cases with symptoms pointing to a certain secretory disorder (as, for instance, hyperchlorhydria, gastrosuccorrhœa continua periodica or chronica) may first be treated without a verifying examination of the gastric contents; but if this treatment proves unsuccessful, an examination of the gastric contents should be made.

The large field in which these examinations of the gastric contents are necessary comprises all chronic affections of the stomach with doubtful diagnosis and which show but slight evidences of improvement. The examinations may help us to recognize the following conditions: 1. Chronic gastric catarrh. Acidity diminished; the ferments present; free HCl variable; mucus present in a large number of cases. 2. Achylia gastrica. Total absence of gastric juice; no HCl; no ferments; total acidity very low, almost neutral. 3. Cancer of the stomach. In many instances incipient cancer of the stomach may be recognized by the constant presence of the following symptoms: free hydrochloric acid absent; lactic acid present; acidity not especially low, sometimes increased; mucus; sometimes small amounts of blackish-looking blood and stagnant food. 4. Hyperchlorhydria. Free HCl present; acidity, 70–140. 5. Gastrosuccorrhœa continua chronica. Presence of about 60–100 c.c. of clear gastric juice in the stomach in the fasting condition. 6. Erosions of the stomach. Presence of a few small pieces of the gastric mucosa in the wash water of the stomach in the fasting condition. 7. Ischochymia. Presence of food in the stomach in the fasting condition.

Often the examination of the vomited matter may do away with the need of obtaining the gastric contents by artificial means. It is, however, readily understood that the vomited matter may occasionally fail to furnish exact data upon the condition of the gastric secretion, as it is likely to be mixed with mucus from the œsophageal walls and the mouth.

While the results of examinations of the gastric contents are useful in aiding to establish the diagnosis in gastric disorders, it is hardly necessary to say that we should not rely upon them alone. We must always combine all the data concerning any given case before arriving at a conclusion. It is only in this way that examinations of the gastric contents will be of great aid to us in helping to establish a more positive diagnosis, and in thus facilitating the treatment.

SLAYERS OF THE WOUNDED.

For a long time the people in this country refused to credit the accounts of attacks by Spanish troops upon Cuban hospitals, and of the butchery by them of doctors, nurses, and patients. The reports were believed to be manufactured in order to arouse sympathy for the Cuban cause, for it was incredible that such savagery could be practised and boasted of as gallant action by any race of white men at the close of the nineteenth century. But the reports became so frequent and so circumstantial that conviction was finally forced upon us, although even then the barbarity was not laid to the account of the Spanish in general, being rather thought to be part of Weyler's policy of murder. Now, however, any lingering doubts as to the truth of these stories and of the Spanish nation's responsibility have been dispelled by the action of the Spaniards themselves in shooting deliberately upon our wounded and their bearers at the battle of Santiago de Cuba.

All accounts of the battle agree in stating that these wretches paid no respect whatever to the Red Cross flag, although they bore unwilling and doubtless unconscious testimony to the honor of our own troops by flying this same emblem of humanity over some of their most exposed blockhouses, filled with gunners and sharpshooters in ambush for our men, thus protecting them from attack. One account says that there were many evidences of dishonorable methods of warfare upon the part of the Spaniards. One of their batteries was masked by a blockhouse over which the Red Cross flag was flying, and the road leading from General Shafter's quarters, on the Rio Sevilla, to the front, had for two days been infested at various points by sharpshooters, who fired deliberately upon our wounded.

The correspondent of *The Sun* says that while he was crossing a stream, leading a mule bearing a wounded Rough Rider, five shots were fired at them. The mule was killed, and Dr. Danford, a surgeon in the cavalry and at one time a surgeon in the Cuban government, was mortally wounded by a bullet passing through his head. A few moments later two other wounded men were shot at the same crossing.

Still another report reads that "one of the most horrible features of the war is the dozens of men who have been killed as they lay in litters, and the surgeons, although wearing the emblem of the Red Cross Society upon their arms, have been the special object of attack."

The Cubans are said to have treated the Spanish prisoners and wounded with equal ferocity, but that can hardly be a matter for surprise. They have the same blood in their veins, and, moreover, they are only doing as they have been done by for years.

The worst enemies of the Spaniards never brought more damaging testimony as to their character than they themselves have done by these and countless other acts of inhumanity. That they are fierce fighters when cornered cannot be denied, but their courage, like their cruelty, is that of the brute or the savage. They have all the qualities of the Turk or the American Indian, with only the thinnest veneer of modern civilization, and the sooner our soldiers learn that Spanish honor is a thing that is not to be trusted, the better it will be for their wounded comrades. It is a blessed thing for humanity and for the cause of civilization that Spain's rule beyond her own peninsula is soon to end, for slayers of the sick and wounded and of the ministers to them have no place among the rulers of the earth.

News of the Week.

The Medical Society of New Jersey held its one hundred and thirty-second annual meeting at Asbury Park, on June 28th, 29th, and 30th, under the presidency of Dr. David C. English, of New Brunswick. The following officers were elected: *President*, Dr. C. R. P. Fisher, of Bound Brook; *First Vice-President*, Dr. Luther M. Halsey, of Williamstown; *Second Vice-President*, Dr. William Pierson, of Orange; *Third Vice-President*, Dr. John D. McGill, of Jersey City; *Corresponding Secretary*, Dr. E. L. B. Godfrey, of Camden; *Recording Secretary*, Dr. William J. Chandler, of South Orange; *Treasurer*, Dr. Archibald Mercer, of Newark. It was decided to hold the next meeting at Deal Beach in June, 1899.

A Large Number of copies of the Medical Record of the issue for July 2d, intended for the subscribers in France, Italy, Switzerland, and Turkey, were included in the mail which was lost on the ill-fated *Bourgogne*. The publishers have arranged to forward duplicate copies by this week's steamer.

Murderers of Surgeons Taken. — Seven Spanish soldiers, who are known to have been in the band of sharpshooters who fired upon our ambulances at Santiago and killed Drs. Danforth and Troval, have been taken by our troops. It is probable that they will be hanged.

Gift of a Hospital to the Red Cross. — Mr. James Armstrong, of this city, has offered the Red Cross Society the use of his country house at Centre Hill, Fla., as a hospital. The house has twenty large rooms, and is built on the highest point of land in the State, about seventy miles from Tampa. It is surrounded by three hundred acres of land, and there is an ice-making plant near by.

The Danger of Yellow Fever in Key West. — There have been two cases of illness recently at Key West, which it is suspected may have been of yellow fever. One of the patients was a sailor on the *Yankee*, who was removed to the hospital for treatment of appendicitis. While recovering from the original trouble he was taken seriously ill and died in two days. The other case was in the person of one of the attendants at the Marine Hospital, and the question concerning the nature of his illness was still undecided when he recovered. Probably neither case was of yellow fever.

Feeding the Reconcentrados. — While prosecuting war against Spain, the government at Washington has not forgotten the main object of relieving the suffering so cruelly inflicted by Spain upon her former subjects

in Cuba. Of course, no relief can be extended to those still shut up in the cities occupied by Spanish troops, but great numbers of the former reconcentrados were driven out from the cities when the war began, and many of these are regularly fed by our government. Frequent expeditions carrying supplies have been landed secretly at various points on the coast, and two vessels are now nearly ready to sail, having on board 750,000 pounds of canned meat, 562,500 of flour, 750,000 of bacon, 90,000 of coffee, 100,000 of sugar, 60,000 of soap, 60,000 of salt, and 3,750 of pepper. The food is distributed in regular daily rations, the ration for each 100 persons a day being 100 pounds of corn meal or 75 of flour, 100 of beef, 6 of coffee, 10 of sugar, 4 of soap, 4 of salt, and 4 ounces of pepper.

Surgeons for New York Regiments.—Adjutant-General Tillinghast has announced the following appointments as a result of the recent examinations: Surgeon of the two hundred and first regiment, William E. Spencer, of Brooklyn; assistant surgeons, L. K. Graves, of New York, and John Wilson Poucher, of Poughkeepsie. Surgeon of the two hundred and second regiment, Daniel S. Burr, of Binghamton; assistant surgeons, James Wood, of Newburg, and Marshall J. Sheldon, of Buffalo. Surgeon of the two hundred and third regiment, Burton S. Booth, of Troy; assistant surgeons, William Alfred Burgies, of Utica, and Abram Lawyer Haines, of Schoharie.

A Red Cross Hospital at Miami.—Mr. Henry M. Flagler has presented to the Red Cross a site for a hospital at Miami, Fla., and has promised to have the first pavilion ready for occupancy within a week and to construct a second as soon as possible. The use of the hospital, fully manned with physicians and nurses, will be offered to the sceretary of war by the Red Cross Society.

General Army Hospital in Old Point Comfort.—It is reported that the government will establish at Old Point a general hospital, where the sick and wounded soldiers will be brought from Cuba for treatment. Tents will be pitched at Fort Monroe, and every provision will be made for the comfort of the sufferers. Twenty surgeons have been secured for service in the hospital.

Dr. James E. Newcomb has been appointed instructor in laryngology in the Cornell University medical department.

Dr. S. C. Ayres has been elected professor of ophthalmology in the Medical College of Ohio, the medical department of the University of Cincinnati.

Obituary Notes.—Dr. John Millspaugh, of Equality, Ill., died at his home in that place on June 17th, at the age of eighty-three years.—Dr. Joseph M. Turner, of Brooklyn, died at the home of his son in Washington, Conn., on July 3d, at the age of eighty-two years. He was a graduate of the medical department of Transylvania University, Lexington, Ky., in 1841, and had practised in Brooklyn for nearly half a century.—Dr. Joseph B. Elliott, a well-known homœopathic physician of Brooklyn, died in that borough on July 3d, at the age of seventy-seven years. He was born in Sharon, Conn., and was a graduate of the Yale Medical School in the class of 1853. He was a descendant of John Elliott, the first missionary to the Indians in Connecticut.

Red Cross Nurses to the Front.—The Red Cross Auxiliary Committee has suggested the sending of one hundred nurses and assistants as near to the scene of hostilities as may be practicable, to the end that they may be accessible for service with the least possible delay, and the relief committee announces that it is prepared to undertake the entire expense of transportation from New York to Tampa and such other places as it may be deemed necessary to send these nurses, and their maintenance while in the field and until their return to New York. Fifteen nurses left this city on July 2d for Cuba, and eleven nurses, two physicians, and two students on July 4th. Preparations are being completed also to send a ship to the Philippines with relief stores for the suffering which reports recently received declare to exist there. The mission has been put in charge of ex-Judge Joseph Sheldon, of New Haven, who will go to San Francisco, to take charge of the fitting out of the proposed expedition.

The Freedom of the City of Edinburgh was conferred on Lord Lister on June 15th.

Hospital Stewards in the Army.—A recent act of Congress fixes the number of hospital stewards in the army at two hundred. Major-General Miles has issued an order calling the attention of commanding generals of army corps to the fact, and saying that, owing to the number of hospital stewards now on duty in the field, ten only will be available for duty with each army corps.

A London Abortionist in the Toils.—An unregistered practitioner in London, who was a notorious abortionist, was recently arrested on the charge of causing the death of a married woman, said to be rich and well known in society, by an attempted abortion. His trial, which was concluded on July 2d, resulted in a conviction of manslaughter and a sentence to seven years of penal servitude.

School Yards as Playgrounds.—In accordance with a resolution passed by the school board for the boroughs of Manhattan and the Bronx, twenty of the public schools were opened as children's playgrounds on Wednesday of this week and will be kept open until September 3d. The board appropriated $15,000 for instituting these playgrounds, and provision was made for maintaining them. Calisthenic drills will be held, but, beyond a little sewing for those who desire it, no work will be given the children. Kindergarten teachers and young men and women recently graduated from college are to be secured as supervisors, instructors, and assistants.

Clinical Instruction for Columbia Students.—It is announced that arrangements have been made for giving clinical instruction to the students of the College of Physicians and Surgeons of New York, at St. Luke's and St. Mary's hospitals.

American Association of Genito-Urinary Surgeons.—At the meeting of the American Association of Genito-Urinary Surgeons, held at Cranston's Hotel, West Point, June 7 and 8, 1898, the following officers were elected for the ensuing year: *President*, Dr. James Bell, of Montreal; *Vice-President*, Dr. Samuel Alexander, of New York; *Secretary* and *Treasurer*, Dr. William K. Otis, of New York. It was decided to hold the next meeting at the Clifton House, Niagara Falls, in May, 1899.

More Hospital Ships.—Bids are now being received by the purchasing agent of the Charlestown navy yard for the furnishings of the new hospital ships, which are to be fitted out there.

Harvard Medical School.—An endowment of $25,000 has just come to the school by the will of the late Dr. Henry W. Williams.

A Physicians' Protective Association.—It is stated in a New York paper that all the physicians of Vineland, N. J., with one exception, have formed a protective association, with a standard scale of fees, and have sent to their delinquent patients notices to the effect that their names will be placed on a black list if satisfactory settlement of accounts is not made before a certain date. The association has requested the council to pay its members half-fees for visits to the poor of Vineland, but certain members of the council, who look upon the protective association as a trust, it is said, talk of engaging by the year the one physician who does not belong to the association.

Nurses from Servia.—It is reported in the papers that the ex-Queen Nathalie of Servia has organized a mission to be sent to the seat of war in Cuba, to give aid to the wounded of the contending armies.

Sobriety in the Volunteer Army.—Dr. N. Senn, of Chicago, chief surgeon, sixth army corps, writes from Chickamauga to the *Journal of the American Medical Association:* "To the credit of our soldiers it must be said that evidences of intemperance are rarely seen in camp. Temperance canteens are common and are better patronized than those in which beer is sold. I have not seen an intoxicated soldier since I arrived in camp."

Medical College Consolidation.—It is announced that the Atlanta Medical College and the Southern Medical College have united to form the Atlanta College of Physicians and Surgeons. Dr. A. W. Calhoun is the president of the new faculty, and Dr. W. S. Kendrick is the dean.

The Latin-American Scientific Congress.—A correspondent of *The Lancet* writes that the first scientific congress which has ever been held in South America, organized by the Sociedad Cientifica of Buenos Ayres, was opened in that city on April 11, 1898. The members numbered about six hundred, and included delegates and visitors from every republic in South America and also several delegates from Mexico, so that the organizers have every reason to be proud of the success which has attended this, the first effort to collect together men of science and learning from the continent of South America. In point of numbers the Argentine Republic heads the list, with over three hundred members; then follow Chili, Uruguay, Brazil, Paraguay, Peru, Ecuador, Mexico, etc. In the medical section many of the subjects discussed were of local interest chiefly, but some are of universal interest, such as leprosy, tuberculosis, vaccination and small-pox, infectious and contagious diseases in relation to sanitary works, subsoil drainage and changes in atmospheric pressure, inoculation in carbuncle and the preparation of anticarbuncular serum, the microbiology and therapeutics of whooping-cough, the *x*-rays in surgery, suicide and mental diseases, and gonococcus—its toxin and serum, etc. The president of the medical sciences section was Dr. R. Wernicke, the secretary was Dr. Araoz Alfaro, and the meetings took place every afternoon from 2 to 7 P.M. The attendance was good and the members were fairly representative, the discussion being carried on chiefly by the younger professors and teachers in the medical faculty and schools.

"Phossy Jaw" is what the English call instances of phosphorus poisoning now being unearthed in some of their large match factories.

The Southern Hospital Train, to be run, when necessity arises, from Tampa to northern points, consists of two dining-cars, ten sleepers, and a baggage car. The sleepers will accommodate five hundred men, if necessary. One car is arranged as an operating-room. The train will be kept at Tampa for the present as a stationary hospital for the sick and wounded, but will be ready at an hour's notice to start north whenever it is thought best to remove the patients to a cooler climate. The Daughters of the American Revolution will keep the hospital train supplied with delicacies for the sick.

Emergency Kits for Soldiers in Battle.—It was intended to supply every officer and man of the invading army under General Shafter with an emergency kit, whereby he might temporarily dress his own wounds when not too severe. Each kit is done up in a waterproof package, and consists of two compresses, one roller bandage, and one triangular bandage. It costs thirteen cents, and sixty thousand of them were shipped to Tampa before the transports sailed to Santiago.

Yaws is one of the tropical diseases with which American physicians will probably be more or less concerned. This prevails to a considerable extent both in the West Indies and in many of the Pacific islands.

Tuberculosis and Vaccination.—The following resolution, introduced by Dr. Pablo Lozano, was adopted at one of the sessions of the International Congress of Hygiene and Demography, held at Madrid during Easter week: "Inasmuch as tuberculosis is easily transmitted by vaccination when it is done directly from the calf, the International Council of Hygiene and Demography asks that in all the nations represented at the meeting the practice should be adopted of using in official vaccination stations only the lymph of calves which have been examined post mortem and pronounced to be free from tuberculosis."

Martyrs to Duty.—Under this heading the *British Medical Journal* refers to two medical men who have recently fallen victims to typhus fever in Ireland. The first was Dr. Paul Dillon, of Killarney, a gentleman who was greatly beloved in his district. He had previously been assistant physician to St. Vincent's Hospital in Dublin, and was a very highly trained practitioner. He was a comparatively young man, having qualified in 1883. He contracted the fever while visiting a poor patient in consultation, and in the same nest two other medical men were also infected, although they have happily recovered. From the north of Ireland the death of Dr. Thomas Sullivan, son of Mr. T. D. Sullivan, M.P., is also announced from the same cause. Here again the disease was the result of a visit to poor dispensary patients, and death resulted in three days. These are fresh instances of the terrible risks which every day threaten the medical man, and from which no fear for personal safety makes him shrink.

English as She is Wrote.—The present Tsar would seem to be not ready to willingly take the position of a figurehead that the hereditary ruler even of an absolute monarchy is more or less relegated to.—*The Philadelphia Medical Journal*, June 25, 1898.

"Anales de la Sociedad Mexicana de Cirujia."—The first number of the Annals of the Mexican Surgical Society, bearing date of June 15, 1898, has been issued. It will be published monthly, under the editorial supervision of Dr. Manuel Barreiro.

Medical Legislators.—The recent election for members of the French chamber of deputies resulted in the return of fifty-seven medical men. The picturesque Mohammedan doctor, whose strict attention to his religious duties amused Paris for a time, was not re-elected.

A Ban against Corsets in Russia.—Hospodin Bogoljewow, the newly appointed Russian minister of public instruction, has begun the duties of his office by issuing a drastic order to the effect that corsets must not be worn by Russian young women attending high schools, universities, and music and art schools. They are to be encouraged to wear the national costume. The minister says that he has spent much time in visiting girls' schools, and has made the discovery that the corset as an article of dress is distinctly prejudicial to the health and physical development of the wearers.

The Toxin of Tuberculosis.—It is reported in the newspapers that a San Francisco bacteriologist has succeeded in isolating the tuberculosis toxin. The method, according to the newspaper account, is as follows: The pure culture is washed in water acidulated with hydrochloric acid. It is then washed again in pure distilled alcohol and then filtered. The filtrate is then distilled, and the residue dissolved in water and precipitated with phosphomolybdic acid. Again the product is filtered and the residue broken up with baryta water. The barium is then precipitated with carbon dioxide. The filtrate is then evaporated and the residue exhausted with alcohol, which gives the alkaloid in a comparatively pure state.

The Indiana Medical Law Sustained.—Judge Howard, of the Indiana supreme court, has affirmed the constitutionality of the law creating a board of medical registration. It had been urged that the law was an improper one, since it interfered with personal liberty, but he said that "whether the law is a wise one is not for the courts to say. It may be that as men are free to choose those who shall minister to the needs of the soul, so also they should be free to choose those who shall minister to the ills of the body. It may be that such laws repress independent investigation, and so retard the progress of medicine. It may be that many of the most valuable medical discoveries were made in spite of the prejudice and protests of men learned in the old and time-tested lore of their day. It may be, finally, that such laws are out of harmony with free institutions, according to which each citizen may pursue his own work, his own studies, his own occupation, in so far as he does not trench on the equal rights of his fellows and the welfare of the community in which he lives. These are, however, questions for the legislature, and, so long as the act is not clearly in violation of any provision of the constitution, it cannot be held invalid."

Foreign Medical Practitioners in Italy.—The Italian government has abandoned its intention of preventing foreign physicians from treating their own countrymen in Italy unless they acquire a diploma from an Italian university. The present law grants them this privilege, but forbids them to give any medical advice to Italians.

The Academy of Medicine of Paris.—For forty years this learned society has had no home, its meetings being held in the old chapel of the Charité Hospital. It owns ground near the Luxembourg, which the government has appropriated for a school of chemistry. In compensation for this lot the French legislature has appropriated a sum sufficient for the purchase of a site for a building on the Rue Bonaparte. On this ground the academy will soon erect a suitable building where its meetings can be held and which then will be used for storing transactions, for the library, or for the various departments which are under the care of the academy—for instance, the vaccination department, the board in charge of prophylaxis and treatment of epidemic diseases, the board to which is intrusted the care of the various mineral springs, the sanitary and statistical departments, and the office for dealing with awards granted for sundry scientific researches.

A Mission Hospital in Tabriz.—A room in the mission hospital in Tabriz, Persia, has been furnished in memory of Mr. Theodore Child, who died there some years ago of typhoid fever, while on a literary mission for a publication in this city. A bronze memorial tablet will be set up on the wall of the ward. The tablet is a relief portrait of Mr. Child, with an inscription in English and Persian.

The Prince of Wales' Hospital Fund has received from a lady, who withholds her name from publication, the very substantial addition of £1,000.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-Fourth Annual Meeting, Held at the New York Academy of Medicine, May 26, 27, and 28, 1898.

First Day—Thursday, May 26th.

DR. G. M. HAMMOND, OF NEW YORK, PRESIDENT, IN THE CHAIR.

Results Obtained by Partial Thyroidectomy in Eight Cases of Graves' Disease.—DR. J. ARTHUR BOOTH, of New York, read a paper with this title (will be published later).

DR. THEODORE DILLER, of Pittsburg, asked whether any bad symptoms developed immediately or shortly after the operation in the successful cases reported by Dr. Booth.

DR. J. J. PUTNAM, of Boston, said he had previously reported two cases of thyroidectomy for Graves' disease, with death following in one instance and gradual improvement in the other. Since then he had had another case, which resulted fatally after the removal of the cervical sympathetic. A very favorable point in connection with the cases reported by Dr. Booth was that the operations were all done by the same surgeon.

DR. WILLIAM M. LESZYNSKY, of New York, said he had had two cases operated on during the past year. In one case there was considerable improvement in all symptoms; in the other the patient died thirty-six hours after the operation. There was no kidney complication and death was ascribed to acute thyroidism. This was a well-pronounced case, and the patient was allowed to rest for nearly two weeks previous to operation.

DR. BOOTH said that, with the exception of a slight rise in temperature, there were no alarming symptoms subsequent to the operation in any of his cases, excepting in the fatal one.

Acute Myxœdema (?) with Tachycardia, Delirium, and Death.—DR. WILLIAM OSLER, of Baltimore, described the case of a man, aged thirty-one, of good family history and good habits, who, from October 1, 1896, to January 1, 1897, increased in weight from one hundred and forty-five to one hundred and ninety-two pounds. Except an occasional attack of diarrhœa and an increasing irritability, there were no symptoms. On February 5th he went to Florida, and there became excited and delirious and had delusions. On his return to his home there was slight exophthalmos. The subcutaneous tissues were everywhere infiltrated, brawny, and did not pit; the skin was dry, and on the chest was a red papular rash. The pulse was 120 a minute. The thyroid gland could not be felt. The temperature was normal. The urine was free from albumin and sugar. For the first two weeks he remained in about the same condition. He had attacks of diarrhœa, and at times there was blood in the stools. On March 1st he was given thyroid extract. He lost rapidly in weight and became delirious. Albumin and sugar appeared in the urine. He grew progressively weaker, and died March 13th. Dr. Osler remarked that myxœdema followed in a considerable number of cases of exophthalmic goitre, and at times certain symptoms of the latter disease had appeared in patients taking the thyroid extract. In this patient there was a rapid increase in the subcutaneous tissue, with a bloated, infiltrated appearance of the face, but not the waxy characteristic facies of myxœdema. The increase in weight and size was remarkable, so that the patient had to have a completely new outfit of clothing. Tachycardia, tremor, and slight exophthalmos supervened, with mental symptoms, coincident with the use of the thyroid extract, of which only twenty-five grains was given. He began to lose weight. Albumin and sugar appeared in the urine. He became delirious and died of exhaustion.

DR. BOOTH referred to one of his cases (the one in which there was no improvement after thyroidectomy), which presented some of the symptoms mentioned by Dr. Oslei. There was a rapid increase in weight, from one hundred and twenty-eight to one hundred and sixty pounds; the face was puffy, and the patient had frequent and severe attacks of diarrhœa and a very rapid pulse.

DR. OSLER thought that in those cases in which sudden death followed operation it was possible there might have been a condition of so-called *status lymphaticus*, in which, as was generally known, sudden death was liable to occur.

Amyotrophic Lateral Sclerosis with Bulbar Symptoms.—DRS. F. X. DERCUM and W. G. SPILLER, of Philadelphia, reported a case of this disease. The microscopical examination showed degeneration of the lateral columns, involving a greater area than that occupied by the crossed pyramidal tracts, and a slight sclerosis of the posterior columns in the lower cervical and upper thoracic regions. The pyramidal tracts were not degenerated above the pons. The bulbar symptoms were due to degeneration of the motor tracts and not of the motor nuclei. The writers discussed the significance of the degeneration in the posterior columns, and showed how the symptoms of amyotrophic lateral sclerosis could exist without degeneration of the pyramidal tracts.

Amyotrophic Lateral Sclerosis.—DR. E. D. FISHER, of New York, read the paper. He considered amyotrophic lateral sclerosis a disease of a character similar to that of progressive muscular atrophy, chronic poliomyelitis, and tabes. All these were simply degenerative diseases of the nervous system. Amyotrophic lateral sclerosis was not an entity, and the name in future would probably be abolished. It was rare, indeed, to find a so-called typical case of progressive muscular atrophy, in which the lesion was confined to the anterior horns. The same might be said of tabes, the lesion extending beyond the posterior columns, involving the lateral tracts, and also the peripheral nervous system. The so-called systemic or tract diseases were relics of an old-time nomenclature, which would ultimately disappear. In all these diseases the physician had to deal with diffuse affections of the spinal cord, medulla, and brain. The author presented microscopical sections from a case which, he said, was a typical clinical picture of amyotrophic lateral sclerosis, and which showed disease of both lateral and posterior columns and the anterior horns.

DR. DERCUM said that the case reported by himself and Dr. Spiller was apparently one of lateral sclerosis, the lateral column symptoms preceding the muscular atrophy. The presence of the bulbar symptoms was probably referable to minute lesions in the border tracts above the nuclei. He was hardly prepared to go so far as Dr. Fisher in regarding tabes as being actually related to the disease known as amyotrophic lateral sclerosis.

DR. CHARLES K. MILLS, of Philadelphia, said that there were three distinct subtypes of this disease. In one type the symptoms of so-called primary lateral sclerosis developed early, with contractures and bulbar symptoms later. In the second type there was muscular atrophy in the limbs, and in the third type the special bulbar symptoms developed very early. He thoroughly agreed with Dr. Fisher that amyotrophic lateral sclerosis should be removed entirely from the classification of spinal diseases; that it could not be regarded as purely cerebral, or spinal, or peripheral,

but should be looked upon as an affection of a special system of neurons attacked by a degenerative process.

Dr. P. C. Knapp, of Boston, believed that, while the three types mentioned by Dr. Mills were now recognized, many transitional types were met with which did not fit any one of them. It must be assumed that there was but one pathological entity.

Dr. H. M. Thomas, of Baltimore, agreed with Dr. Knapp. He thought that amyotrophic lateral sclerosis was a bad name, combining, as it did, a symptom and a pathological finding in one term. It would be better to consider these conditions as due to degenerative lesions in the motor tract, which were simply variations of one and the same trouble—sometimes beginning in the upper motor segment, sometimes in the lower, and usually involving both.

Syringomyelia and Tabes with Sensory Dissociation on the Trunk.—Dr. Hugh T. Patrick, of Chicago, reported a case of syringomyelia showing analgesia of almost the entire trunk, including the arms, with a narrow zone of tactile anæsthesia about the middle of the body, such as had been recorded by Lachr and the author as occurring in this disease. Two cases of locomotor ataxia that presented almost the same sensory conditions were then described. This sensory dissociation on the trunk was opposed to the rule in tabes, for in this disease the sensory blunting on the trunk was usually a tactile anæsthesia with no analgesia whatever or only a comparatively narrow zone in the middle of the anæsthetic area where pain sense was lost. One of the cases of tabes, however, presented atrophy of one trapezius muscle and deformity of one foot, conditions almost identical with those seen in the patient with syringomyelia. This tabetic patient had, besides, suffered spontaneous gangrene of two toes, a complication much more characteristic of this latter disease than of locomotor ataxia.

Syringomyelia with Unusual Symptoms. — Drs. William N. Bullard and John J. Thomas, of Boston, reported the case of a boy, previously healthy and of fairly healthy antecedents, who, when three years old, became subject to attacks of headache of much severity, lasting an hour or more; these were soon accompanied by vomiting, and increased in frequency and severity. This condition continued three years, growing gradually worse, and at the end of that time staggering was noticed and a severe double optic neuritis occurred, which soon produced double optic atrophy and nearly total blindness. The headaches, vomiting-attacks, and blindness continued much the same for nearly two years—the remainder of the patient's life. At times the pain and prostration were such that he was in bed for days or weeks at a time; then he would improve, and would be able to be up and about like a healthy child. During this time there was great increase in the general adipose tissue, so that the patient became obese, and to this condition were added later exophthalmos and an appearance suggesting myxœdema. These two symptoms, however, disappeared after a month or two. During the first part of this time (in March, 1895) there was temporary paresis of both external recti and nystagmus. There were no further changes in the symptoms until about ten months after the blindness began, when there was a sudden attack of paraplegia, accompanied by incontinence of urine and fæces, which became permanent. At the same time there appeared a paralysis of the left face and some weakness of the upper extremities, but these soon disappeared. Bedsores developed, but later improved, and the child was in good general condition although the obesity had somewhat diminished at the time of death, the result of typhoid fever.

At autopsy there was found a marked dilatation of the ventricles, including the fourth, and of the iter, resulting from the hydrocephalus. The branching cavity in the cord seemed to originate in the gray matter and not to be a diverticulum of the central canal, although at the point of greatest dilatation of the cavity in the lower cervical region the central canal opened into and became a part of the general cavity. Above the point of greatest dilatation of the cavity there was an ascending degeneration of the direct cerebellar tract, the tract of Gowers, and the posterior columns. Below this point there were marked degeneration of the direct and crossed pyramidal tracts, and diffuse atrophy of the posterior columns. There was also well-marked atrophy of the tract of Gowers. At the point of greatest dilatation of the cavity there were extensive degeneration of all the fibres of the white matter of the cord and marked distortion of the gray matter, in which, however, fairly normal nerve cells were found in moderate numbers. There were diffuse increase of neuroglia fibres in the atrophied tracts, and marked neuroglia proliferation about the cavity in the cord.

Dr. Knapp, of Boston, said that the study of sensory disturbances, especially in tabes, showed that they did not follow any definite course. As a rule, in tabes the analgesia was more extensive than the anæsthesia. It had long been a question in his mind whether analgesia was the result of a slight disturbance of the sensory tract and anæsthesia the result of a much greater disturbance, or whether two separate tracts, one for pain and one for anæsthesia, were being dealt with.

Dr. B. Sachs, of New York, thought the view that the well-known sensory symptoms of syringomyelia were almost pathognomonic of that disease could no longer be entertained. He had observed two cases of Potts' paralysis with dissociated sensory symptoms confined to the extremities. In two other cases there was dissociated sensation in the distribution of the trigeminal nerve. He inquired whether such cases had been observed by any one else.

Dr. Frank R. Fry, of St. Louis, said that he had seen two such cases in addition to one case which he had already reported.

Dr. Patrick, in closing the discussion, said he did not agree with the statement of Dr. Knapp that in tabes, as a rule, the analgesia was more extensive than the anæsthesia. On the trunk tactile anæsthesia was more extensive than the analgesia, and appeared sooner. The ordinary dissociation of sensation on the extremities in Pott's disease was not very uncommon.

Landry's Paralysis.—Drs. Charles K. Mills and W. G. Spiller, of Philadelphia, reported a case in which paralysis developed very rapidly in a man previously healthy, and after one week the man died, completely paralyzed in all the extremities. Sensation was preserved until death. One of the external popliteal nerves examined was found degenerated, and the motor cells of the spinal cord presented the lesions known as central chromatolysis. The writers reviewed the cases published in the literature, and discussed the value of central chromatolysis as indicative of secondary changes within the cell body. They believed that transitional forms of acute ascending paralysis occurred, which made the diagnosis between Landry's paralysis, polyneuritis, and myelitis difficult. Landry's paralysis might be due to myelitis or to neuritis, and it was possible that in some cases no lesions could be found.

Dr. Mills held the view that in many of these forms of acute toxæmia or infectious disease it was very probable the entire peripheral motor neuron—or whatever system was affected—was attacked at one and the same time.

Congenital Facial Diplegia.—Dr. H. M. Thomas, of Baltimore, reported the histories of two brothers, aged twenty-one and nineteen respectively, who showed this remarkable defect. The family history was un-

important, except that the mother's aunt had given birth to a deformed child and that the mother herself had had a baby with a deformed foot. The birth of the elder boy was difficult, but no instruments were used. That of the second boy was normal in every respect. In each case it was noted shortly after birth that the baby was unable to close his eyes and that the lower lip drooped. Except for the facial deformity, the children developed normally. There was nearly complete bilateral facial paralysis, the patients being able only to retract and depress the corners of the mouth. Combined with this there was partial deafness in both ears and the lobes of the ears were misformed. Movements of the eyeballs were perfectly normal and no other abnormality was discovered. Dr. Thomas brought these cases into relation with the cases of congenital facial paralysis combined with defect in the movement of the eye muscles, and with a few cases of uncomplicated unilateral congenital facial paralysis, and less directly with congenital muscle defects in other parts of the body. In regard to the pathological basis of the condition, nothing definite could be said, as there were no unequivocal autopsies. He believed that it was most satisfactory to assume a maldevelopment or a non-development of the nuclei of these nerves.

Dr. Spiller, of Philadelphia, referred to the relationship between the condition described by Dr. Thomas and progressive muscular dystrophy of the Landouzy-Dejerine type. In the latter affection the orbicularis palpebrarum and the muscles about the mouth were the ones usually involved, and the affection might exist for years without atrophy of any other muscles.

Dr. Sachs, of New York, considered that the muscular element was very much more at fault than the nuclear. These cases were not necessarily neural in origin; while some of them might be, others would show that only the muscular or osseous systems were involved.

Dr. Thomas said that the question of the probable relationship between this condition and progressive muscular atrophy was not new. He regarded the symptoms in his case as congenital, and expressed the opinion that it would be unusual to see a case of muscular dystrophy of the facial type which dated from birth and persisted until the twentieth year without affecting any other nerves.

Multiple Syphilitic Neuritis.—Dr. Frank R. Fry, of St. Louis, read the notes of a case of this sort. A man, thirty-two years of age, contracted syphilis in the fall of 1896. A year later he had a sudden right hemiplegia, the face escaping. The paralysis was slight, the patient walking with a hemiplegic gait and retaining considerable use of the hand. The knee jerk and the wrist jerk on the paretic side were exaggerated. Three weeks later a paraplegia developed, which became complete and was followed by marked weakness of the hands, with hyperæsthesia and paræsthesia in all the extremities. The knee jerks were lost, and later there was reaction of degeneration in the muscles of the legs. After eight weeks improvement began, and it had been continuous. He had since been able to resume his business. The diagnosis was based on the characteristic sensory symptoms—reaction of degeneration, absent knee jerks, the extensive distribution and peripheral character of the paralysis, and the manner in which the paralysis and sensory symptoms cleared up, leaving no evidence of focal lesion of the central nervous system. It was assumed that the neuritis was due to syphilis, because no other cause seemed apparent. There was nothing in the patient's habits or occupation which predisposed him. He was not an alcoholic and had no rheumatic tendency. Mercury was used by inunctions, but a severe constitutional effect was not produced, nothing more than a slight sensitiveness of the teeth. The drug produced no cachexia or local lesions in the joints or elsewhere, although it was used freely after the neuritis appeared.

Dr. C. L. Dana, of New York, said that his experience with multiple neuritis and with syphilitic affections of the nervous system led him to regard it almost as a pathological law that multiple neuritis never resulted from syphilis. In order to prove such a case, every other possible cause of the neuritis must be excluded.

Dr. Sachs, of New York, thought Dr. Dana had stated the other side of the case a little too strongly. He was of the opinion that the evidence of a multiple neuritis or a peripheral neuritis of syphilitic origin had been fairly well established.

Dr. M. A. Starr, of New York, agreed with Dr. Dana, and said that, although he had been on the watch for a case of multiple neuritis of syphilitic origin during the past ten years, he had never seen one which he was willing to pronounce as distinctly syphilitic.

Dr. J. J. Putnam, of Boston, held the same opinion as expressed by Drs. Dana and Starr.

Dr. Leonard Weber, of New York, said he could not recall a single case of multiple neuritis occurring in a series of one hundred and twenty-five cases of syphilis which had been under his observation more or less constantly for nearly twenty years.

Dr. Fry, in closing, said he had expected that his diagnosis would be criticised. In the case under discussion the history and symptoms had led him to the belief that the neuritis was of syphilitic origin. He was, of course, unable to establish the fact positively.

Herpes Zoster.—Dr. Leonard Weber, of New York, read a paper with this title (see page 39).

Dr. J. J. Putnam, of Boston, was inclined to believe that the lesion in these cases was far back, although perhaps not so far back as the ganglion.

Dr. Spiller, of Philadelphia, said that these cases certainly seemed to be connected with disease of the nerves, especially of the sensory branches. He did not know of any case in which the motor fibres alone were involved.

Dr. W. M. Leszynsky, of New York, said that in recent years he had come to regard herpes zoster as one of the symptoms of a peripheral neuritis, and he treated the patient accordingly with excellent results. For the purpose of relieving the acute pain, especially in the intercostal variety, he had found the use of the Paquelin cautery remarkably efficacious. One application to the spine in the region of the corresponding posterior roots was often sufficient to relieve the pain, and in most cases rendered special internal treatment unnecessary.

Dr. Sinkler agreed with Dr. Weber's view, that in herpes zoster the lesion was not always a peripheral one, but might be situated in the cord or in the ganglion.

Dr. C. L. Dana believed that in most cases the trouble was in the nerve; probably in the sensory branch and deeply seated. It was not uncommon to see these attacks followed by severe forms of neuralgia, affecting either the intercostal, crural, or trifacial nerves.

Dr. Weber, in closing the discussion, said that, as none of his cases had come to autopsy, he could not tell whether they were of local or of central origin. He believed, however, that certainly one-half of the cases were of peripheral origin.

Purulent Internal Pachymeningitis, Complicating Middle-Ear Disease.—Dr. William Leszynsky, of New York, reported the following case: The patient was a man, twenty-three years of age, who had been affected for many years with chronic suppurative otitis

of both ears. He complained of pain in the right ear and tenderness over the mastoid region. There were also rigors, high temperature, and sweating, indicating a probable infective sinus thrombosis. The mastoid and sinus were explored with negative result. The same symptoms continued unabated, and subsequently he developed increasing hebetude, double optic neuritis, motor aphasia, right facial paralysis, and right hemiplegia. There was no disturbance of sensibility. The patient never complained of headache, nor were there any other symptoms indicating an acute involvement of the left ear. The left temporo-sphenoidal lobe was thoroughly explored for an abscess formation, but none was found. Death occurred twenty-four hours later. The autopsy revealed purulent internal paehymeningitis limited to the dura over the left Rolandic region, and softening of the central convolutions on the same side. On the left side the tympanum was entirely destroyed by caries, and the sinuses were completely disorganized, while on the right side the sinuses were normal. Dr. Leszynsky dwelt at length on the difficulties so often met with in making a correct localization in cases such as that reported.

Dr. E. B. Angell, of Rochester, had had under his care a patient who had previously been treated for middle-ear trouble. Subsequently delirium set in, but there were no focal symptoms. The general symptoms were those of pyæmic infection. The question of opening the skull and searching for pus was considered, but recovery finally took place without operation.

Dr. G. L. Walton, of Boston, said that Macewen had shown that temporo-sphenoidal abscess extending inward affected first the leg, then the arm, and finally the face; extension upward following the inverse order. In the case under discussion the arm received the brunt of the injury, which made the diagnosis more difficult. His own experience with a case of tumor in this locality tended to confirm Macewen's rule.

Dr. Leszynsky, in closing, said that the course of the paralysis in his case would not permit exclusion of temporal abscess, as an abscess in that location might involve the arm and face more than the leg. While Macewen's views and experience might apply to his own cases, the speaker thought they could not be accepted as an absolute law.

Serous (Alcoholic) Meningitis Simulating Brain Tumor.—Dr. Theodore Diller, of Pittsburg, reported a case of this nature. The patient had been getting progressively worse for six months, presenting during this time severe headache, frequent vomiting-attacks, failing vision due to optic neuritis, weak ataxic gait, loss of knee jerks, tenderness in the legs and burning in the feet, and finally general convulsions followed by marked mental changes. It seemed quite plain that the man was suffering from multiple neuritis due to alcoholism. The ataxic gait, weakness, wasting, and tenderness of legs and burning of feet with diminished knee jerks were explained by this diagnosis. There remained, however, the headache, vomiting, optic neuritis, convulsions, and mental symptoms to be accounted for. These seemed to indicate the presence of a brain tumor, although the fact was recognized that the mental symptoms were very similar to those seen in alcoholic multiple neuritis. The autopsy failed to reveal a brain tumor, but disclosed great dilatation of the pial vessels with a large amount of clear colorless fluid beneath the pia. There was intense congestion of the pia in several spots, but only a little more than the usual amount of fluid was found in the ventricles.

Dr. W. L. Worcester, of Danvers, was in doubt whether the post-mortem findings accounted for all the symptoms. An exudation of serous fluid into the meninges did not necessarily imply an inflammatory condition, although it might have done so in this case.

Dr. Dercum, of Philadelphia, said it was a well-known fact that serous meningitis was very apt to be mistaken for brain tumor. In this form of meningitis there might be diffuse headache, a high grade of optic neuritis, and nervous manifestations which were often suggestive of tumor.

———

Second Day—Friday, May 27th.

Myotonia.—Dr. George W. Jacoby, of New York, read a paper with this title. He considered Thomsen's disease (myotonia congenita) a clinical type, to which nothing could possibly be added; the term should, however, be limited to the actually congenital cases of myotonia, and should exclude all others. For the latter some other designation must be sought. It would be better to class all cases under the generic term myotonia, and then to subdivide into myotonia congenita, myotonia acquisita, and myotonia transitoria. Cases which presented only spasm upon voluntary movement, but no myotonic disorder or reaction, should be classed as intention spasm. He related the histories of three cases, two of which had previously been presented at a meeting of the New York Neurological Society. These cases illustrated the various types of myotonia. In one case, in which the patient acquired the disease at the age of eighteen, after an attack of typhoid fever, pieces of muscle were excised and subjected to microscopical examination. Transverse and longitudinal sections gave the microscopical picture of the changes hitherto considered pathognomonic of Thomsen's disease. Dr. Jacoby concluded that the proof of the myopathic nature of this affection, derived from examination of excised pieces of muscle, was insufficient, and that the changes thus found were due to the abnormal contractility of the muscles in this disease and merely corroborated the clinical fact of this hypercontractility. Whether the hypercontractility was due to a disorder of the muscular or of the central nervous system could therefore not yet be stated. The fact that one of the cases occurred after an attack of typhoid fever led Dr. Jacoby to inquire whether such an accidental cause in the form of any acute infection might not frequently be the actual productive agency of the disease, such infection acting upon inherently weak nerve cells. The knowledge of the pathogeny of myotonia must remain obscure until a careful cytological examination of the brain and spinal cord had been made.

Dr. G. M. Hammond, of New York, presented three children, all members of the same family, as cases illustrating a myotonic disorder. The disease did not manifest itself until their eighth year. Previous to that age they appeared to be like other children, excepting that they were very dull and could not get along at school. All three had a peculiar facial expression; they were depressed and subject to violent crying-spells at the slightest provocation. One of the girls had been subject to chorea, and subsequently developed the myotonic disorder. The disease in these cases was entirely confined to the hands and arms. The hand could readily grasp an object, but there was difficulty in letting go of it. The mental deficiency in these cases seemed to indicate some degenerative cerebral change, perhaps in the pyramidal cells of the cortex.

Dr. Theodore Diller, of Pittsburg, said he had examined the first patient referred to by Dr. Jacoby, and there was in addition to the other symptoms a distinct spasm of the extrinsic ocular muscles and of the orbicularis palpebrarum. The case did not impress him as being of psychical origin.

Dr. W. G. Spiller, of Philadelphia, had seen two

cases in which an intention spasm was present. One was a case of syringomyelia, and the other of brain tumor. According to present knowledge of the subject, myotonia and muscular dystrophy presented many features in common. In the only case of Thomsen's disease in which a necropsy was obtained—that of Dejerine and Sottas—the lesions in the muscles were very similar to those described by Dr. Jacoby.

Dr. Jacoby concluded that under the classification of myotonia only those cases should be included which presented certain definite symptoms. In addition to the intention spasm there should be an absence of anything pointing to gross disease in the central nervous system.

Amaurotic Idiocy.—Dr. Frederick Peterson, of New York, presented the report of a case with autopsy. The patient was a little over seven months old at the time of death, and was one of three amaurotic idiots in a family of five children. The child presented the usual symptoms of the disease, and died of bronchopneumonia following measles. There were never any symptoms of organic brain lesion. At autopsy the brain was found to show grossly the usual features of defective development. The pathological changes in the case were limited to the nerve cells of the cortex and medulla, which were found markedly deficient in number and in development in the occipial region, about the calcarine fissures, in the temporo-sphenoidal lobes, in the frontal lobes, in the motor areas, in the corpora quadrigemina and geniculate bodies, and in the third and fourth cranial nerve nuclei. The alterations of the chromatic substance of the cells must be referred largely to the general condition of the patient before death and not to the disease under discussion. The lesions in the chromatic substance in the atrophic cells could not be accurately determined. No definite changes in fibres or tracts were discovered.

The Pathological Anatomy of Amaurotic Family Idiocy.—Dr. William Hirsch, of New York, read a paper with this title, and reported the case of a child, ten months old, who had died after being under observation one year. The autopsy was made four hours after death. The microscopic examination revealed very marked changes in all the nerve cells of the entire central nervous system. Serial sections had been made through the spinal cord, the medulla oblongata, corpora quadrigemina, optic thalamus, caudate nucleus, cerebellum, and through the entire cortex of the brain, and not a single normal cell was found. All the nerve cells were enormously enlarged; the cell body was swollen, in some instances to three times its normal size. The Nissl granules were transformed into a pulverized mass. The nucleus with its nucleolus was displaced to the periphery of the body. The processes were very few in number and often broken off. There were degeneration of the pyramidal tracts in the spinal cord and medulla oblongata and atrophy of the optic nerves. The neuroglia and the blood-vessels were perfectly normal throughout the entire nervous system. The clinical evidence as well as the anatomical findings proved that the assumption that the disease consisted of an arrest of development was erroneous, and showed that the disease was an acquired one. The typical change in the nerve cells, and the fact that all the nerve cells and nothing but the nerve cells of the entire nervous system were affected, made it very probable that the condition was a toxic one, with a direct action of some poison on the nerve cells.

Dr. Ward A. Holden, of New York, then made a report on the pathological findings in Dr. Hirsch's case. The changes in the eyes were confined to the ganglion cells of the retina. In sections of a Müller's-fluid eye the ganglion cells were enlarged and globular but had central nuclei; stained with Weigert's hæmatoxylin or with hæmatein, they appeared filled with black metaplasm granules. In formol sections of the eye, cut in paraffin and stained by Nissl's method, the ganglion cells appeared to consist only of the cell reticulum (Nissl granules being absent) and a darkly stained granular nucleus. These staining-reactions were identical with those given by the cortical cells of two brains of amaurotic idiocy—one hardened in Müller's fluid, one in formol—with which the eye preparations were compared. In the normal eye the ganglion-cell layer about the fovea was but three or four cells deep, and farther away it thinned down rapidly. The gray patch seen about the fovea in this disease was one and one-half to two disc diameters in width, and faded out gradually at its periphery into the normal red of the fundus. It occupied that portion of the retina in which the ganglion-cell layer was four or more cells deep, the swollen ganglion cells rendering the retina opaque and obscuring the red color of the choroid except in the fovea, where ganglion cells were wanting. There was no actual œdema, as had been supposed, and the other layers of the retina were normal. In the optic nerve there were a breaking down of the myelin in many fibres of each bundle and an increase in neuroglia tissue—a secondary degeneration of the neuraxons of the affected ganglion cells of the retina and of the basal ganglia. The retina, which, the speaker said, arose, like the brain, from the involuted neural ectoderm, and was also histologically analogous to the cerebral cortex, here exhibited a primary pathological change in its neurons similar to that found in the cerebral neurons.

Dr. B. Sachs, of New York, said he was firmly convinced that amaurotic family idiocy was a morbid entity, which he hoped would be placed upon a firmer basis by the extensive pathological studies made by Drs. Hirsch, Holden, and others. As children so affected grew older, both the mental and the physical deterioration became more marked, and many of them died in a condition of marasmus. He did not think there was a great difference between arrest of development and degeneration. If there was an arrest of development, a degeneration necessarily followed, and for that reason there was not such a radical difference in the interpretations put upon the cases. He did not believe that a disease so widespread as this, which began at the same period of life in different individuals and which involved some members of the family and left others exempt, could be due to any toxic influence.

Dr. Carl Koller, of New York, said he had seen five cases of this affection. In his opinion the characteristic ophthalmoscopic changes in the macula were not congenital, and were not found up to between the fifth and seventh months. In two of Kingdon's cases, that were examined in the first month, they were missing, and in two of his own cases examined in the first two months of life they were also absent. One of the latter was the case reported by Dr. Peterson. Dr. Koller had examined the child five times between the eighth and sixteenth weeks of its life, the ophthalmoscopic result being negative, although other unmistakable signs made him sure that it was a case belonging to this class. In the other case the characteristic changes developed later. The atrophy of the optic nerve, he said, made its appearance a considerable time after the changes in the macula, and developed gradually. The behavior of the children with regard to their vision was not normal at a time when no ophthalmoscopic changes were visible, so that the conclusion was permissible that vision had been impaired by cerebral degeneration.

Dr. C. K. Mills, of Philadelpiha, said that these cases, along with some of the forms of diplegia and of muscular atrophy, belong to a great embryonal class. The potentiality of development in these cases was

limited, and it might be weeks or months or years before the symptoms made their appearance. Whether the pathological conditions which gave rise to the lesions were toxic or non-toxic, sooner or later the degenerative process would manifest itself.

Dr. F. X. Dercum, of Philadelphia, had one family under his observation in which out of four children three suffered from spasmodic diplegia and idiocy. The symptoms of the degenerative process manifested themselves immediately after measles, while the only child that escaped in the family did not have measles. He thought this tended to strengthen the toxic theory of amaurotic family idiocy.

Dr. Hirsch, in closing the discussion, said he could not dispense with the distinction between a congenital and an acquired condition. He did not question the fact that children who developed amaurotic family idiocy were born with a normal nervous system. He agreed with the previous speakers that the toxic origin of the disease was still an open question. He took exception to the statement that amaurotic family idiocy was in line with other hereditary diseases. He knew of no other inherited family disease in which all the nerve cells in the body became affected. The condition, so far as he knew, had no analogy in pathology.

Formation and Excretion of the Metaplasm Granules of the Neuron.—Dr. Ira Van Gieson, of New York, made some remarks on this subject, illustrated by drawings on the blackboard and numerous microscopic specimens. He first described the constituents of the ganglion cells, referring to the sap, by which the food coming to the nerve cell was elaborated, and the reticulum, which transmitted the impulses and also subserved the phenomena of retraction and extension of the neuron. When the food supply of the ganglion cell was diminished—as in alcoholism, in overfatigue, etc.—an indication of the deficiency was presented in an excretion of particles which escaped from the cell, passed out of the lymph space, and clustered about the blood-vessels. These metaplastic elements were the results of overfatigue—of a diminished food supply to the nerve cells. These nerve changes were not altogether of toxic origin. The quantitative and qualitative food supply of the cells must be taken into consideration. In amaurotic family idiocy there was an indication of a diminished food supply to the cells.

Locomotor Ataxia with Hepatic Crises.—Dr. William C. Krauss, of Buffalo, reported a case of locomotor ataxia in a woman, aged forty-three years, who for ten years had periodic paroxysmal attacks of jaundice with intense hepatalgia, which the writer designated "hepatic crises." The patient had the lancinating pains in her limbs, with myosis, Argyll-Robertson pupil, loss of tendon reflexes, marked ataxic gait, and inco-ordination. Every four or five weeks she had attacks of deep jaundice, with excruciating pain over the liver, clay-colored stools, and presence of bile pigment in the urine. These attacks would last two or three days, then disappear for a month. The hepatic area was not enlarged. No gall stones were found in the fæces. There was no rise of temperature, and the patient died in one of these attacks. The autopsy revealed the characteristic changes of locomotor ataxia in the spinal cord and spinal ganglia. The liver weighed three and one-fourth pounds, and showed no new growth of any kind. The gall bladder was filled with bile, but no gall stones were found. The ductus choledochus and accessory ducts were unobstructed. The microscopical examination showed an early stage of chronic congestion of the liver.

Dr. William Osler, of Baltimore, thought that the pain and jaundice accompanying the attacks would lead one to suspect the presence of gall stones. Although no gall stones were found post mortem, that did not exclude the possibility that they were present during life and gave rise to the hepatic symptoms.

Dr. Krauss replied that the fæces were examined almost every day, but no traces of gall stones were found.

Nosology of the So-Called Functional Diseases.—Drs. Joseph Collins and Joseph Fraenkel, of New York, presented a paper with this title. The authors endeavored to prove that the various so-called functional nervous disorders were primarily conditioned through the sympathetic system, and were the result of a trophic change.

Dr. Dercum said he did not think there was a scintilla of evidence that the sympathetic system played the extensive rôle assigned to it by the readers of the paper.

Dr. Ira Van Gieson considered the sympathetic as that part of the nervous system which covered the whole question of food supply. He thought the authors had attempted to show that in certain diseases there were changes in the higher spheres of the nervous system, produced by lesions of the sympathetic, either functional or organic, which had deprived those higher centres of their food supply.

Dr. Mills thought the authors of the paper had made the mistake so often made, of attributing to a certain portion of the nervous system diseases which largely manifested themselves through such portion. They had done little more than to assert that certain diseases were traceable to the sympathetic nervous system. To a certain extent, the paper was a step backward. There was quite as much evidence in favor of designating hysteria as a cerebral or psychic disease as for calling it a disease of the sympathetic nervous system. He felt that the authors had failed to clear up the mystery surrounding the present knowledge of the diseases of this system of nerves.

Dr. Sachs said that ignorance of the functions of the sympathetic nervous system was not entire. It was known that certain pupillary and visceral symptoms, as well as certain vasomotor and trophic symptoms, had their origin there. He did not think the writers of the paper would be able to prove that such symptoms occurred more frequently in hysteria or in neurasthenia or in acromegaly than in diseases positively known to be of cerebro-spinal origin.

Dr. Osler regarded the paper as a retrograde step, in again bringing forward an old and defunct theory. Still, he said, it only went to show that men of to-day had the same thoughts their fathers had.

Dr. J. J. Putnam said that while he did not regard the sympathetic system as an essential factor in the causation of disease, he did regard it as a very important factor in the maintenance of certain diseased conditions.

Dr. Collins, in closing the discussion, said he did not wish to maintain that any of the diseases he had mentioned were diseases of the sympathetic system. He maintained only that they were nutritional diseases, and that the sympathetic nervous system controlled nutrition from beginning to end.

Family Periodic Paralysis.—Dr. E. W. Taylor, of Boston, read a paper with this title. The condition, he said, consisted of periodic attacks, at varying intervals, of a complete flaccid paralysis of the muscles of the body and extremities. Associated with this paralysis there was an impairment of electrical excitability of the muscles and nerves, varying from temporary quantitative diminution to complete loss. There was also a loss of the reflexes. During such an attack consciousness and sensation were unaffected. The patient's condition between attacks was normal. The condition was clearly a family disease. The cases reported by Taylor occurred in a family in which in five generations there had been eleven cases. The

two persons studied were brother and sister, both of whom suffered from attacks of the above type. The brother, chiefly studied, presented a perfectly typical variety of the affection. The etiology was lacking, excepting in the one particular that the attacks generally came on after exercise followed by rest. The pathological anatomy was as yet vague.

Dr. Sinkler said he wished to place on record a case that had come under his observation. The patient was a man with facial paralysis, who gave a history of five previous attacks in the course of ten years. Each of the attacks lasted several weeks and ended in complete recovery.

Dr. Dana had seen a number of cases of periodic paralysis, none, however, of the family type. He had come to the conclusion that, while some of them were cases of recurrent poliomyelitis, the majority were purely hysterical in character. The family type of this disorder was certainly rare, and perhaps a little light might be thrown upon the subject by studying allied conditions. He had seen a number of patients who had informed him that when they first awoke in the morning they were unable to move for half an hour or even longer, suffering from paralysis and a certain amount of numbness. The ordinary types of morning paralysis seemed to be the result of some toxic condition associated with an asthenic condition of the nervous system.

Dr. Collins said he had observed three cases of periodic paralysis, none, however, of the family type.

Dr. Taylor, in closing the discussion, said he thought the cases which had been mentioned by the various speakers were not absolutely analogous to those reported in his paper.

Surgery and Pathology of the Gasserion Ganglion.—Drs. W. W. Keen and W. G. Spiller, of Philadelphia, presented a communication on this subject. Dr. Keen had operated on the ganglion in eleven cases. He believed that the removal of the ganglion was almost invariably attended with the relief of pain; that it was hardly practicable to attempt to preserve the motor root; that it was better to remove the whole rather than only a part of the ganglion; and that, as the removal of the ganglion was always a serious undertaking, it was best to do a peripheral operation first, unless the pain was widespread and involved all three branches of the nerve. He thought that peripheral operations should be done when the disease had existed for three or four months and had not been cured by drugs. The microscopical examination by Dr. Spiller of seven ganglia removed by Dr. Keen showed intense alteration of the ganglia, involving axis cylinders, myelin sheaths, blood-vessels, and the connective tissue. In one case, in which the entire ganglion with its motor and sensory roots was removed, these roots were found to be normal, although the second and third branches of the nerve near the ganglion were greatly degenerated. The writers believed that trifacial neuralgia was primarily due to disease of the peripheral branches of the nerve, and that the ganglion was probably secondarily involved. In a case in which only the supra-orbital and infra-orbital nerves were removed, these nerves were found much degenerated.

Dr. Mills said he considered the paper the most valuable that had ever been made conjointly to the surgery and pathology of this important subject. He was inclined to the opinion that tic douloureux in the typical form in which it was commonly seen was a degenerative process of the peripheral sensory neuron. He did not regard it as a neuritis, in the ordinary sense of the term.

Dr. Dana agreed with Dr. Spiller as to the pathology of this condition. He believed that the specimens and investigations confirmed the views of Dr. Putnam and himself, that in most of these cases it was a degeneration of the nerve that had to be dealt with. Tic douloureux was a disease not only of the nerve, but of the whole individual. In quite a number of cases it was a self-limited disease. He was opposed, as a rule, to surgical interference.

Dr. Van Gieson had found in these cases an obliterating endarteritis of the vessels accompanying the nerves and a proliferation of the nerve cells. He looked upon the disease of the vessels as the primary cause of the changes in the nerve fibres.

Dr. Keen, in closing, said that the question was purely a clinical one. He did not agree with Dr. Dana regarding the unsatisfactory results of operative interference in these cases. His own experience had convinced him to the contrary.

Dr. Spiller concluded that this disease was usually a peripheral one. If the lesion was primarily in the ganglion, it was difficult to understand why the peripheral branch of the nerve was so highly diseased, while the central branch was normal.

Third Day—Saturday, May 28th.

Long Remissions in Epilepsy, and their Bearing on Prognosis.—Dr. Wharton Sinkler, of Philadelphia, read a paper based on a study of twenty-four cases of idiopathic epilepsy, in which there had been remissions of the attacks of periods varying from two to twenty-nine years. In none of these cases was trephining done. In a few of these cases the freedom from attacks was attributable to the long-continued use of remedies, but in the majority of cases as soon as the attacks were arrested all medication was stopped, and therefore the relief from the seizures could not be ascribed to treatment. In his opinion the conclusion to be drawn from a study of the twenty-four cases presented was that epilepsy should be regarded as an incurable disease. It was encouraging, however, to find from the long intervals which had occurred in these cases that the disease was amenable to treatment, and that a sufferer from epilpesy might look forward to the probability of long remissions, in which he was as competent to fill his place in the world as if he had never had the disease. None of the authorities on the subject of epilepsy who had been consulted had expressed an opinion as to what should be considered a cure in epilepsy, nor had they paid any attention to the occurrence of long periods of freedom from the attacks, with the exception of Niemeyer and Gray. The former in a general way had said that "long remissions might occur" and the latter writer that "cases might be free from attacks for ten, fifteen, or even twenty years," and that he had known in his own practice "remissions of several years."

Huntington's Chorea.—Dr. Frank K. Hallock, of Cromwell, read a paper on this subject and presented the report of a case which showed clearly the course and order of development of the degenerative process, the dementia and chorea paralleling each other as the degeneration progressed. Viewed psychologically, the chorea was seen to be of secondary importance to the underlying dementia, thereby warranting the descriptive and pathologically more correct name of "dementia choreica." In discussing the applicability of the term "dementia" to Huntington's chorea, he stated that there need be no doubt as to the prognosis, course, futility of treatment, and termination of the disease. Given the heredity and the characteristic chorea appearing in middle life, the prognosis could be stated with a surety fully equal to that accorded dementia paralytica and dementia senilis. The conclusions reached were: (1) That it was a progressive degenerative disease of the brain, fundamentally different from the ordinary or Sydenham's chorea; (2) that the chief physical manifestations of the disease were the chorei-

form movements, which were of secondary importance, indicating merely the nature of the cerebral lesion; (3) that the character of the mental symptoms could best be described by the term dementia; (4) if the above assertions could be verified, then the disorder should be classed with such diseases as dementia paralytica and dementia senilis.

Regeneration of Nerve Fibres in the Central Nervous System.—Dr. W. L. Worcester, of Danvers, read a paper with this title. He said that in an old case of necrosis of the right corpora quadrigemina he found in the degenerated portion several bundles of contorted fibres, entirely dissimilar to any normal structure in this region, and resembling an amputation neuroma. They seemed to originate from the tegmentum above the red nucleus. He believed them to be an outgrowth of newly formed fibres from neurons that had been interrupted by the lesion.

Localization of the Sympathetic Nerve in the Brain and Spinal Cord.—This was the title of a paper read by Dr. B. Onuf, of New York. It consisted of a report of experimental researches, with contributions to the physiology of the sympathetic.

The discussion was participated in by Drs. Spiller, Booth, Langdon, and Collins.

The Neurological Aspect of Public-School Education.—Dr. John Punton, of Kansas City, read a paper with this title. He believed that serious defects still existed in the routine methods of public-school education and training of the young, which were attested not only by the general public but also by the teachers and officers of schools. Moreover, all recognized that marked constitutional differences and defects existed in both mind and body in children of every class of society, but the special relation which they bore to modern educational methods was not so well understood as it should be. The vital relation of these lesions of organization to the proper protection and health of the race on the one hand, and the prevailing vices and social evils on the other, together with their special relation to public-school education, presented a phase of the subject which so far had received but little attention in America, but which really constituted the neurological aspect of education. What was necessary to be done, nay, even demanded, was to fix certain definite standards of weight and measurements for every age and height; any pupil found to be above or below this standard should be treated accordingly. In almost every city in the world anthropometrical investigations had now been made, and the unanimous verdict had been reached that the mental output of the pupil was directly related to his height, weight, and physical measurements, and that there was a physical basis for precocity on the one hand and mental dulness on the other.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. J. Hendrie Lloyd, of Philadelphia; *Vice-Presidents*, Drs. Frank R. Fry, of St. Louis, and Henry Hun, of Albany; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York; *Councillors*, Drs. F. X. Dercum, of Philadelphia, and G. L. Walton, of Boston.

Infant Feeding.—Dr. L. Emmett Holt (*Archives of Pediatrics*, November, 1897) concludes as follows: 1. That good breast milk is the best infant food. 2. That no substitute for breast milk can be trusted which does not furnish essentially the same elements—fat, sugar, proteids, etc.—as breast milk. 3. That these elements are found only in the milk of other animals, cow's milk being the only one available for general use. 4. That cow's milk requires some modification before it is fed to infants.

Therapeutic Hints.

Cold Sponging versus Cold Bath.—Dr. H. A. Hare (*Therapeutic Gazette*, March 15th) affirms that he has used cold sponging in his hospital practice and rarely the bath, with the most satisfactory results. He suggests the following rules of treatment: 1. In early typhoid, with constipation or moderate diarrhœa, give a full dose of calomel in divided doses, in order to stimulate the liver and antisepticize the bowel with bile. 2. Control the fever when it reaches 102° F. by sponging. The patient being stripped and laid on a rubber sheet or blanket over a sheet, he is to be sponged with water adapted in its temperature to his needs, and it is to be remembered that the rapid application of a low temperature is more refreshing than the prolonged application of a higher temperature (Baruch). The chief advantage of the cold sponge lies in the shock and reaction. This is better obtained by the use of ice sponging than by the bath. The patient's surface is always bright red in ice sponging, often blue in the bath, and that the fever is not the chief danger in the case renders the fact that as great a reduction from the sponge is not reached as from the bath of little importance except in hyperpyrexia. Shattuck tells us that he has found no marked or constant difference in the antipyretic value of cold sponging at 60° F. for twenty minutes, the cold pack at 60° F. for sixty minutes, or the cold bath at 70° F. for ten or fifteen minutes. Finally, if this does not bring the temperature down to 100.5° or 101° F. in twenty minutes, resort should be had to the tub. It is essential when the sponging is used that more water be applied to the back than to the trunk of the body, for at the back the great muscles and thick skin retain the heat as a reservoir, and are not cooled if only the front of the body is sponged. Further, the posterior surfaces are the ones apt to be congested and sore, from the dorsal decubitus, and therefore need the stimulating effect of the bath, as do the kidneys and other deeply situated organs. That this treatment is of value is shown by the marked redness of the skin, the improvement of the circulation and respiration, and the cleared mind. 3. It is advisable not only to use friction in a light form, but to use moderately active massage, with the same objects in view as when the rest cure is undertaken, for the proper treatment of typhoid is a modified rest cure. The writer is firmly convinced that by this means bedsores, local congestions and effusions, œdematous swellings, peripheral nerve pains, and muscular feebleness will be largely decreased, and Pospischl has shown that mechanical irritation of the skin is capable of increasing heat loss ninety-five per cent. 4. In nearly all cases give more nourishment than the average typhoid patient in the past has usually had. With the exception of broths and meats, almost any article easy of digestion should be allowed—as one or two or more lightly boiled eggs, cornstarch, arrowroot, etc. 5. Use stimulants in carefully graduated doses whenever the circulation needs them, particularly alcohol. Even the cold-bath enthusiasts give whiskey to overcome the depression they often produce.

Thrombosis and Embolism of the Mesenteric Blood-Vessels present a condition not so rare as journal articles would imply, yet nevertheless it is one seldom recognized either during life or after death. Its principal symptoms consist of intense abdominal pain, bloody diarrhœa, subnormal temperature, sometimes with vomiting, perhaps in the later stages vomiting of blood. Shock is usually also extremely marked. The consequence of this condition is almost inevitably gangrene of the intestine supplied by that particular

portion of the mesenteric vessels. The pain comes on a short time after the occurrence, and under the peculiar circumstances gangrene may be practically determined within fifteen hours. More than fifty cases of this kind are now on record in surgical literature, and the condition is one well worthy the attention of the surgeon, because only by surgical intervention—*i.e.*, by resection of the necrotic mass of intestine—can life possibly be saved. Thus Elliot (*Annals of Surgery*, January, 1895) successfully resected one and one-fourth metres of intestine for this purpose.—Dr. Roswell Park, "A Treatise on Surgery," vol. i., p. 40.

Peritonsillitis.—For several years I have treated all cases coming under my observation by thoroughly cleansing the throat and nose with a mild alkaline solution, followed by the application of spirits of turpentine and compound spirits of lavender, equal parts, disguising the taste by the addition of a few drops of the oil of anise or gaultheria. This is applied to all the inflamed tissue, as thoroughly as possible, with cotton on a fine applicator—behind the soft palate, into the crypts of the tonsil, and when possible between the tonsil and the pillars of the fauces. I order the patient to apply the above mixture every one or three hours. A mercurial followed by a saline laxative is usually indicated. Give as much nourishment as can be taken, either hot or cold, as most comforting to the patient. If an attack is seen early, this treatment will abort it; later, it will prevent the formation of pus and the involvement of the opposite side. It will in nearly all cases prevent involvement of the opposite side, even though pus be already present.—Dr. K. W. Baldwin, *Journal of the American Medical Association*, March 12th.

Pruritus Opii.—In exceptional cases both opium and morphine produce a rash accompanied by intense itching. The "pruritus opii" has been frequently noticed, and is described as an annoying and unbearable affection. The rash presents a scarlatinoid appearance, and even the mouth and throat may be attacked by erythematous inflammation.—William Murrell, "Manual of Pharmacology and Therapeutics," p. 296.

Phthisical Cough.—In the hacking, irritable cough of phthisis, unattended with much expectoration:

℞ Codeine ..... gr. iv.
Diluted hydrochloric acid..... ʒ ss.
Spirits of chloroform..... ♏ iss.
Syrup of lemon ..... ♏ i.
Water..... ad ʒ iv.
Make an emulsion. A teaspoonful frequently, when cough is troublesome.

—Murrell.

Rhagades.—

℞ Lævulose..... 10
Aquæ destillatæ 100
S. Apply twice daily.

—*Allgemeine medicinische Central-Zeitung*, March, 1898.

Treatment of Metrorrhagia during the Menopause.—Orloff (*Klinisch-therapeutische Wochenschrift*, No. 7, 1898) uses injections of alumnol and tincture of iodine in the metrorrhagia of the menopause. After a vaginal irrigation with a five-tenths-per-cent. solution of bichloride and cleansing of the orifice with a five-per-cent. carbolic tampon, he inserts a cannula into the uterus and through this injects slowly a solution of alumnol and tincture of iodine (alumnol, 2.5; tincture of iodine, 25; absolute alcohol, 25), by means of an intra-uterine syringe. At the beginning injections are undertaken daily; later every second day. After ten or twelve injections the bleeding ceased and the menstruation appeared too late rather than too early.

Hemorrhage of Trauma and Menorrhagia.—Reverdin (Geneva) recommends the sulphate of sodium internally in doses of half a gram every hour.

In the Diphtheria of Adults.—

℞ Tinct. aconiti..... ..... 20 gtt.
Tinct. belladonnæ..... 1 gm.
Glycerini..... 15 gm.
Aquæ gaultheriæ dest..... 120 gm.
M.
Or:
℞ Potassii chloratis,
Sodii bromidi,
Liq. ferri sesquichloridi..... ..... āā 1.8
Glycerini..... 15
Aquæ dest..... 120
M. S. To be given alternately every fifteen minutes in half-teaspoonful doses.

—Douglass, *Journal de Médecine de Paris*, 1897, No. 2.

For Dyspepsia with Flatulence.—

℞ Tinct. gentianæ,
Tinct. valerianæ,
Tinct. nucis vomicæ. ..... āā 4
Chloroformi..... 20–40 gtt.
M. S. Ten to twenty drops in water before meals.

—*Centralblatt fur die gesammte Therapie*, 1897.

An Antiseborrhœic Hair Wash.—

℞ Chloralis,
Ac. tartarici..... āā 1
Olei ricini..... 0.5
Spiritus vini rect..... 100
Essentiæ flor. æth..... 9.5

—Eichoff, *Deutsche medicinische Wochenschrift*, 1897.

A Painless Vesicant Plaster.—

℞ Menthol,
Chloral..... ..... āā 1
Spermaceti..... 4
Cacao butter..... 2
M. S. Spread on a piece of linen.

—*Allgemeine medicinische Central-Zeitung*, No. 20, 1898.

In Purulent Cystitis.—

℞ Acidi salicylici,
Acidi boracici..... āā 5
Aquæ fervidæ..... ad 1,000
M. S. For irrigation of the bladder.

—Rabaw *and* Bourget, *Memorabilia*, August, 1897.

An Antiseptic Vaginal Douche.—

℞ Naphthol *a*..... 3
Alcohol..... 26
Distilled water..... 1,000
M.
Or:
℞ Betanaphthol..... 5
Alcohol..... 30
Aquæ dest. calid..... ad 1,000
M.

—*Allgemeine medicinische Central-Zeitung*, No. 20, 1898.

For Hemorrhoids.—

℞ Extr. hamamelidis virgin.,
Extr. hydrastis canadensis,
Tinct. benzoini comp..... āā 16
Tinct. belladonnæ..... 4
Olei olivæ carbolisati (5 per cent.)..... 32
M. S. Local application.

—Adler, *Journal de Médecine de Paris*, No. x., 1897.

Myringitis Chronica Sicca.—

℞ Acidi sozoiod..... 0.25
Alcohol. abs..... 1
Ol. ricini..... 10
S. External use.

—Stetter.

Uric-Acid Diathesis and Nephritic Colic.—

℞ Lithii iodidi..... 75
Mucil. gum tragac..... q.s.
Ft. pil. No. 50. S. One pill three times a day.

—Ruhemann.

Hyperidrosis of the Hands.—

℞ Boracis,
Acidi salicyl.....āā 15
Acidi boracici..... 5
Glycerini,
Alcohol. dilut.....āā 60
S. Apply three times a day.

—Mode.

Bronchitis.—

℞ Terpin..... 5
Glycerini,
Spirit. rectif.,
Syr. simpl.....āā 70
S. Tablespoonful three times a day.

Or:

℞ Terpin,
Acidi benzoici pur.....āā 0.1
Opii pur..... 0.01
For one pill. Four such daily.

—Lyon.

Articular Rheumatism.—

℞ Acidi salicylici,
Olei terebinthinæ.....āā 10
Lanolin..... 30
Ung. paraffini..... 50
M. S. Apply externally.

—Ziemssen.

Croupous Conjunctivitis.—

℞ Acidi carbolici..... 1
Cocainæ muriat..... 0.3
Glycerini puri..... 30
S. Apply externally.

—Samek.

Syphilis.—

℞ Iodi..... 1
Potassii iodidi.....q.s. ad sol.
Glycerini..... 5–10
Acidi citrici..... 15
Syrupi simplicis..... 1,000
S. Begin with two tablespoonfuls daily and increase to six.

—Bonveyron, *Lyon Médical*, January, 1898.

Laxative Pills for Children.—

℞ Ext. casc. sagrad..... 2
Ext. frangulæ..... 1
Pulv. aloes,
Pulv. gentian.....āā 4
M. ft. pil. No. 80. S. 1–4 pills at night.

—Pruys.

Ozæna.—

℞ Creosoti..... 5
Alcoholis (70 per cent.)..... 10
Glycerini puri..... 40
M. S. Apply with tampon to crusts.

—Ferreri, *Archivio Italiano di Laringologia.*

Nerve Pain.—

℞ Syrup. thebaic..... 50
Tinct. camphor..... 30 gtt.
Chloral. hydrat..... 2
Aq. chloroformi saturat..... 120
S. Tablespoonful every two or three hours.

—Holz.

Scarlet Angina.—

℞ Aq. oxygen..... 30
Sodii bicarb..... 12
Aq. dest. coct..... 60
S. Irrigate the pharynx every two hours.

—Clanahan, *Journal de Médecine de Paris.*

Nervous Pruritus of the Menopause.—

℞ Zinci oxidi..... 0.3
Quin. sulphat..... 2.4
Aloin..... 0.15
Extr. et pulv. liq..... q.s.
Ft. 20 pil. S. One pill three times a day.

—Shoemaker.

Ulcus Cruris Varicosum.—

℞ Sodii chlorat. subtill. pulv..... 50
Menthol. pulv..... 5

—Simonelli, *Journal de Médecine de Paris*, No. 48.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

UTERINE FIBROMA—POST-GRADUATE CLASSES—AN EXHIBITION—IRISH COLLEGE—HOSPITAL MATRONS—LONDON HOSPITAL—BRITISH MEDICAL ASSOCIATION—"NINETEENTH CENTURY" BOOKS—APPOINTMENTS—DEATHS, HENRY LEE AND OTHERS.

London, June 17, 1898.

Considerable difference of opinion was expressed at the Obstetrical Society in reference to the treatment of uterine fibromyoma. Dr. Herbert Spencer related two cases in women under twenty-five years. In one he had amputated after laparotomy; in the other vaginal hysterectomy had been done after the peritoneum had been opened in an attempt to enucleate the tumor. He gave an abstract of forty recorded cases in women under twenty-five. In eleven of these the diagnosis was clinical, and in only four verified by the microscope. He found no satisfactory record of a case occurring before puberty, and the disease is rare under twenty-five.

Dr. Herman approved enucleation in certain cases, and in that of Dr. Spencer the patient had recovered just as well as after abdominal hysterectomy and without the scar of that operation.

Dr. Horrocks pointed out that these tumors were associated with active menstrual life.

Dr. Lewers agreed with Dr. Herman as to enucleation. He thought the risk was not great when the largest diameter of the fibroid projected free into the uterine cavity, and not more than one-third remained embedded in the thickness of the uterine wall. When the largest diameter of the tumor remained in the thickness of the wall, he thought enucleation very dangerous.

Dr. Cullingworth was quite opposed to enucleation, which he had found more dangerous than removal of the entire uterus. Though enucleation might succeed with highly skilled operators, it could not be commended for general adoption.

Dr. Spencer, however, maintained that enucleation had given him very good results and was not so dangerous as represented. He admitted, however, that in one case a large part of the wall had been removed with the tumor and he had had to suture the aperture, but the patient did well; also that enucleation would be dangerous unless complete.

These admissions seem to show that inexperienced operators might easily be landed in a very awkward position in attempting enucleation.

Post-graduate classes do not seem to have caught on with us, and our efforts in this direction have been feeble compared with yours. We have, indeed, several sets of lectures and demonstrations connected by feeble ties and pushed by a few interested persons. But it is difficult to be sure that there has been any advance since these formed a loose kind of union, the chief value of which seems to be to facilitate advertising the instruction available. The graduate who desires to extend his knowledge of any department can select the special hospital he prefers, and will be welcomed as a student there, and this was the case before any attempted union to imitate the American plan. A scheme, however, is now on foot for establishing a medical graduate college and hospital, on a plan that may vie with the States. It is supposed there will be sufficient support for such a development, but I doubt if the promoters have sufficiently weighed the cost. After the full curriculum of five years now required, the young graduate may well think he has had lecturing enough, and if he feels defective in one specialty he

can attend for a time the department at his own school or can frequent a special hospital, where he can observe the latest methods employed by the staff. If he has time and opportunity, he can attend two or more special hospitals and see the practice. It is scarcely to be expected that any new institution can be officered by a staff which all round can compete with the united teachers of all the special hospitals. It is hardly to be expected that the profession will subscribe to the necessary funds, and the cause is not likely to enlist the sympathy of the public.

Roused by the scheme for a central institution, the West London Hospital is crying out that it has for years been the nucleus of a post-graduate hospital, and requires only the money to complete its arrangements. This hospital has grown rapidly of late years, and will soon have one hundred and fifty beds open. On its staff are some able and energetic men, who would like to extend their opportunities for teaching and are ready to make it a school exclusively for graduates. A few years ago they wanted to make it a junior school, but ambition grows. They have a laboratory for pathological and bacteriological work, and other attractions. They will not find it easy to make all departments as complete as the several special hospitals do. If they do we shall see whether the newly fledged graduate will forsake his own school, where he can continue to study without further payment, to fly to the new institution and pay fresh fees. If he cares only to take out one course, he will find a special hospital more economical.

The medical, surgical, and hygienic exhibition, lately held here, was so successful that the promoters announce that they will hold one annually. London is certainly large enough to support such an institution, and it would seem that many practitioners like to take a stroll through an exhibition and notice the novelties. The annual museum of the British Medical Association is, of course, held at the varying meeting-places, and never fails to attract a large number of members, but it must be remembered these gentlemen are then on their holidays. Whether they will spare time to look in during their season of work, is another question. There is a certain sameness in these exhibitions—the same instruments, drugs, chemicals, foods, mineral waters, and so on; but every here and there something fresh appears to keep up the observer's interest. This last exhibition was particularly strong in dietetic preparations, though pharmacy was also well represented.

Three gentlemen have announced their determination to contest the next election for the vice-presidency of the Royal College of Surgeons in Ireland two years hence. It seems a long enough notice to give.

The matrons of our hospitals have held a conference, and seem to have agreed that nurses should all be trained, examined, and registered. Examination is the popular panacea for everything, and registration next. A beginning might be made by examining the matrons.

At a quarterly special court of the London Hospital, it was decided on Wednesday to adopt the system of requiring small payments from out-patients.

The arrangements for the meeting of the British Medical Association are rapidly approaching completion. Edinburgh offers innumerable advantages for such an assembly, and a successful meeting is anticipated.

The *Nineteenth Century* this month contains an article on "Death and Torture under Chloroform." One anticipates from the title a diatribe on vivisection, especially as it is written by a woman; but it is really an attempt to show that many administrators of anæsthetics do not understand their work and inflict horrible sufferings on the patients. Mrs. King calls them "stiflers," and displays so much ignorance of her subject that one can only wonder by what accident the article passed the editor. Its tone throughout should have warned him.

Dr. Macewen's "Pyogenic Diseases of the Brain and Spinal Cord" has been translated into German.

Mr. Harrison Cripps will shortly publish a volume devoted to his own experience and methods in abdominal surgery.

Dr. W. W. Ireland has in the press a work on the mental diseases of children.

Dr. Beattie Crozier has a new book nearly ready, which is to be called "My Inner Life—a Chapter in Personal Evolution."

Martindale and Westcott's "Extra Pharmacopœia" is ready, in a new issue embracing the changes of the new B. P.

Sir William Turner received on Wednesday the honorary D.Sc. of Cambridge University.

Lord Lister is to receive the corresponding honor from Victoria University in October, when he is to open new laboratories at the Liverpool College. Meantime he was, on the 6th, enrolled as an honorary fellow of the Glasgow Faculty of Physicians and Surgeons. His lordship must by this time be surfeited with the honors conferred upon him.

Dr. Bloxall has been appointed superintendent of the new laboratory for the preparation of glycerinated calf lymph.

Sir J. A. MacCullagh, M.D., Dublin, has been appointed an inspector under the Irish local government board. He was knighted at the Queen's jubilee.

Dr. Niven, M. O. H. for Manchester, has been appointed a lecturer in the Victoria University. He was already lecturer in Owens' College.

Death, ever busy in our ranks, takes one and another, young and old. Of the former I have to name two in Ireland, who have both died of typhus contracted from poor patients. One was Dr. T. D. Sullivan, son of the M.P. of the same name; the other, Dr. Paul Dillon, of Killarney. Dr. Fitzpatrick, of Dublin, was a nonagenarian, having been born in 1806, and of course had retired for a long time.

On the 11th instant died Henry Lee, consulting surgeon of St. George's Hospital, where he was originally a pupil and afterward surgeon. He was also for a number of years surgeon to the Lock Hospital, and had filled other important offices. He was an important figure among London consulting surgeons, and retained his vigor of mind to a late age. He retired only a few years ago, and was eighty-one at his death. You know much of his work as a syphilographer and operator, as well as contributor of valuable works on surgical pathology and practice. He wrote the treatise on venereal diseases in Holmes' "System of Surgery." His operation for varicose veins is familiar to most, and his success as an operator, especially in joint excision, well known. He introduced calomel fumigations and was *facile princeps* in the treatment of syphilis. Perhaps his work was mostly so good because it was founded on pathology, in which from student days he was profoundly interested. A pleasant companion, a stanch friend passes away in the genial Henry Lee, who ever held the sincere regard of his numerous pupils and colleagues. Twenty years ago, having passed his sixtieth year, he thought well to make room for younger men, but he kept in private practice for a considerable period after that.

Puerperal Eclampsia.—After morphine and chloral had failed, veratrum viride, ℥xx. every six hours, and subsequently ℥xl. every four hours, was followed by marked improvement.—J. B. SHOBER, *American Journal of Obstetrics*, June, 1897.

OUR PARIS LETTER.

(From our Special Correspondent.)

CHRISTIAN SCIENCE AND VIOLATION OF THE LAW REGULATING THE PRACTICE OF MEDICINE—BUREAUCRACY AND HOSPITAL MEDICAL SERVICE—ANENCEPHALUS—BICARBONATE OF SODIUM IN THE TREATMENT OF CHARBON—THE TREATMENT OF DIPHTHERIA, ETC.

PARIS, June 18, 1898.

THE practice of Christian science is regarded here by some of the leading members of the medical profession as an infringement upon or a violation of the law regulating the practice of medicine. The point has been made and the question is now asked: What constitutes illegal practice of medicine? The law exacts of whoever practises medicine on French territory two conditions: 1st, to be provided with a French diploma of doctor of medicine, or officier de santé; 2d, to be inscribed on the official lists. Therefore, whoever practises medicine on French territory without complying with both these conditions is liable to prosecution for the illegal practice of medicine. Doctors, regular graduates of a French faculty, who do register their diplomas at the Palais de Justice and have their names duly enrolled on the official lists, are also liable under the law. The practice of medicine *per se* is not confined merely to examining patients and writing prescriptions for them, nor to surgical manipulations or operations, strictly speaking; but extends to all kinds of medical advice — palpations, manipulations, examinations, the giving of electricity, magnetism, and whatever act or acts may pertain to healing or a method of cure. Exception is made in favor of curates, officiating priests, and sisters of charity, who, giving advice and care to their ill parishioners, neither signing prescriptions nor holding consultations, and giving their services gratuitously, are only doing acts of charity, which the law does not forbid and which the administration sanctions. If, therefore, the Christian science "dodge" is a method of cure or pretends to be such, as it certainly does, it is a violation of the French laws regulating the practice of medicine, and those practising it are liable to prosecution under them. Furthermore, it is not only habitual practice without a diploma that the law punishes; one act alone may render the offender liable to a condemnation.

This brings me to the subject of bureaucracy in the larger hospitals of Paris; that is to say, business administration and management *vis-à-vis* of medical service. The continual warfare of the man of science and learning against red-tapeism is waged with more or less vigor, according to the spirit of despotism or autocracy of the powers that be or the overexacting and cross-grained character of the individual. I am speaking generally. There has, however, been of late years a marked improvement and more harmony in this respect in Parisian hospital administration. When a patient is brought or comes to a hospital, it is the duty of the interne on service to indicate briefly the nature of the case for classification, thus: "fever," which is equivalent to saying, "This is a patient for the medical wards"; or "wound," signifying that he or she should be turned over to the surgeons. It thus happened at the "Pitié" one day that a jealous and overbearing director forbade the internes receiving urgency patients without putting on the bulletin an accurate diagnosis of the disease. The internes, chafing already under too much "bossism," complied immediately, and all the bulletins of urgency patients admitted from that day bore the diagnosis, "anencephalus," an absence of brain, of which the administration had given abundant proof. The director was at first much pleased at the punctiliousness with which his orders had been carried out. But he soon became anxious, then frightened. Anencephalus continually! It must be a terrible and unknown disease, invading the capital. He called his personnel around him and ordered the most rigorous prophylactic measures to be taken. Still the disease followed its course, and he discovered to his horror that there were one hundred and thirty cases of anencephalus on the books of his hospital alone. The explanation had to come, and the laugh was turned prodigiously on the director, who got off by withdrawing his order and leaving the internes to classify their patients as they had been doing previously.

Bicarbonate of sodium seems to be good for almost everything; it corrects acidity, promotes nutrition, is an excellent remedy for colds, and efficacious externally in the treatment of burns and other surgical diseases. Dr. Camescasse, at a recent meeting of the Therapeutical Society in Paris, stated that he had obtained a very rapid cure in two cases of charbon (or pustule maligne) by keeping applied to the tumor, after having incised and painted it with tincture of iodine, cloths wet with a solution containing twenty grams of bicarbonate of sodium in a litre of lukewarm water. This solution had already been employed with success by Dr. Gueorguievsky in the treatment of phlegmons, panaris, and, in general, all suppurative wounds.

Dr. Barbier considers that in the treatment of diphtheria special indications are furnished by the degree of intoxication of the organism, as well as by certain infections associating their action to that of the bacillus of Loeffler. Thus microbial associations render the subject more sensitive to diphtheritic poisons, and the bacillus itself is more active. In cases of diphtheria with multiple agents of infection, recourse must be had to antiseptic irrigations of the nose and throat. Diphtheritic intoxication will not only benefit by anti-diphtheritic orrhotherapy, but also by exhibiting therapeutic agents not less special (I do not say specific), such as artificial serum, caffeine, and digitalis. Certain nervous phenomena are best combated by preparations of strychnine. In a word, symptomatic treatment is indicated in most accidents or complications in the course of diphtheria. This is a return to the good old doctrine of treating symptoms. It goes without saying that diphtheritic cases ought to be isolated, whether with associated infections or not; and as regards all diphtheria the most strict hygiene and prophylaxis must be exercised in private practice, and with all the more reason in the hospital.

THE SEAT OF INFECTION IN THE EXANTHEMATA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In an interesting article on antitoxin rashes, by Dr. Berg, in the MEDICAL RECORD of June 18th, I notice in the last paragraph, first column, page 870, the following statements:

"It would appear possible that in these diseases [measles, varicella, variola, and scarlet fever] the characteristic germs, having gained access to the blood, develop there their toxic products; every effort is made by the excretory functions of the body to get rid of these toxic agents. The excretory power of the skin, kidneys, and mucous membranes is brought into play; hence the characteristic manifestation in all of these organs in the course of these diseases; thus the eruption and catarrhal inflammation of the mucous membranes characteristic of measles, the eruption and characteristic inflammation of the throat, and later on of the kidneys in scarlet fever."

Now this paragraph being somewhat in the nature of a *capitulo a parte*, any remarks upon it will not affect the value of the main part of Dr. Berg's article, and, while the statements found in this paragraph are the

general belief, they are nevertheless unfounded and incapable of demonstration. In the first place, it has never been shown that the germs characteristic of measles, varicella, variola, and scarlet fever gain access to the blood and develop there their toxic products. On the contrary, the living blood is recognized either as a bactericidal fluid or as one capable of inhibiting the growth of germs. It is true that the plasmodium malariæ is at times found in the blood in great numbers, but the exact nature of this parasite has yet to be determined, and the theory that the blood and not some lymphatic tissue is its breeding-ground is not yet proven. It is almost a self-evident truth that the blood has and must have an inhibitive influence on germ life. If it were not so, general sepsis would be the result of every local infection.

In the second place, I wish to criticise that part of his paragraph which intimates that the catarrhal inflammation of the mucous membranes in measles is the result of the excretion of toxin. I believe that the mucous membrane of the respiratory tract is the seat of infection in measles, and that beyond this membrane the germs never go. I furthermore believe that the inflammatory condition of this membrane is due to the exciting presence of the germ, and, as the mucous membrane of the throat is primarily an absorbing membrane, it is reasonable to suppose that the toxin is not eliminated here, but by the skin and kidneys, which are the two great excretory tissues of the body.

In the third place, the same criticism is extended to the remark on "the eruption and characteristic inflammation of the throat, and later on of the kidneys in scarlet fever." The eruption in the throat and the inflammation of the kidneys in scarlet fever are the result of entirely different causes. The eruption in the throat is due to the germ; the inflammation of the skin and kidneys is due to the toxin. In the MEDICAL RECORD of January 15th I presented the view that scarlet fever is a local disease of the throat, and since then I have learned that I am not alone in my belief.

LUKE FLEMING, M.D.

TARRYTOWN, N. Y.

Medical Items.

Casualities of a Small Boy for One Week.—S. M. Worthington, M.D., of Versailles, Ky., writes: "My legacy to posterity, S. M. W., Jr., aged one and one-half years, swallowed a pin on Sunday; passed it on Monday. Swallowed three pins and five buttons on Tuesday; passed them all in one action on Wednesday. On Thursday, procuring my hypodermic syringe case, he took an unknown quantity of tablets of morphine, gr. $\frac{1}{4}$, and atropine, gr. $\frac{1}{150}$. By constant attention through that day and night he sufficiently revived to be taken riding on Friday. The horse shied. The hub shot through, throwing all out of the cart, and, catching in the felloe, dragged the wheel flatwise. When I regained my feet the horse was running furiously up the rocky road, the boy lying on the wheel. Some sixty yards away he slid off on the roadside grass, without injury of any kind. On Saturday he rested from his labors in casuality. Sunday returning, he went with me to church and proved the promise, 'He giveth his beloved sleep.'"

Jubilee of Modern Spiritualism.—The jubilee of modern spiritualism was celebrated at the beginning of April in Manchester. Mrs. E. H. Britten, of Manchester, described as a "notable apostle of spiritualism," opened a four-days' jubilee bazaar and international fancy fair, the object of which was to raise £2,000—a very material agent—toward a propaganda fund to promote the spread of spiritual knowledge and enable those who sit in the valley of shadow, in fear of death and the hereafter, to realize that man is a spirit, naturally immortal, progressive, and responsible; that there are no dead—all live; and under favorable conditions can communicate with their friends and loved ones and help, guide, comfort, and bless them. On the platform there was a reproduction of the frame house at Hydesville, N. Y., where, on March 31, 1848, it is stated, "the spirit by raps responded to questions, and established a method of intercourse which has been adopted in all parts of the world." It is remarkable that the spirits in America—that ingenious and labor-saving land—should invent so clumsy a mode of sending messages from another world. Mrs. Britten declared, "after nearly forty years' experience, . . . that it was the first scientific religion that the world had ever known, and came from the source of all light—God, our heavenly Father, and from none other." She told how Victor Hugo had said to her again and again: "There is no more death; that which is called so is a splendid success"—a remark characteristically French. During the afternoon a great tea meeting was held, and this was followed by a mass meeting in the evening, at which three thousand people were present. The chairman, a Mr. Wallis, said that while fifty years since there were no spiritualists in their sense of the word, to-day there were millions all over the world. According to another speaker, much has been done by the movement, for it "had had to educate the church and men of science and the general population as well." But most of all, as he said, "they had had to educate their own party and to develop their spiritualists out of the spiritualism that the angels brought to them from the spirit world." This was a task, and it is wonderful how Mr. Moore and his friends did it, even with the help of the angels. Many of these people are no doubt sincere and belong to the so-called educated classes, but education does not necessarily confer wisdom and judgment in the sifting and weighing of evidence. It would be impolite to speak of "cranks," and yet there is an old saying—"there's nothing so queer as folks."—*The Lancet.*

A New Disease to the magistrate was that advanced by a prisoner last week as an excuse for intoxication. Magistrate Kudlich is well up in medicine and fully appreciates the necessity of taking a little spirits with a dose of quinine to break up a chill or ward off a cold. When, however, caisson disease was pleaded as an excuse for falling into the hands of the police, the justice was for a moment in doubt. So good a clinical account of the effects of working in compressed air was given by the man, however, that he was released and a note was made by the judge to look the matter up in the books.—*The Sun.*

Winkler's Reaction: A New Test for Free Hydrochloric Acid in the Stomach Contents.—A small quantity of the normal filtered stomach contents, to which a few grains of dextrose has been added, is poured out on a clean porcelain plate; add a few drops of a solution of alphanaphthol, and heat gently. A violet-blue color is developed, which rapidly changes to inkish black. Or a standard test solution may be kept on hand, made by adding to a five-per-cent. alcoholic solution of naphthol α one-half to one per cent. solution of grape sugar. As in the Günzburg and the Boas tests, so also in this one there is a negative reaction if, instead of free hydrochloric acid, sulphuric or phosphoric acid is present.—*Centralblatt für innere Medicin.*

Mud Baths were common among the ancients, the mud on the seashore and the slime of the rivers being especially prized for this purpose. The Egyptians still use them for certain complaints, such as gout and sciatica.

Navy Full-Diet Table.—After much study the medical officers of the navy have adopted a new full-diet table, in which every care has been taken to provide for a proper quantity of proximate principles in a variety of food suitable for a liberal diet, says the *Army and Navy Journal*. For each meal in the table running through a week the precise amounts of albuminoids, carbohydrates, and fats were arranged, bearing well in mind the preferences developed by a seaman's life. The bills of fare represent not only the ideal poor man's food, but food that cannot be surpassed by royalty as well. It is found in practice from the returns of all hospitals that these meals cost an average of thirty cents per day per person, or about ten cents per meal. The tables are thought to constitute the best possible fare, and represent a most excellent foundation for carrying other gastronomic luxuries. The naval full-diet table is as follows for one day in the week, the number after each article relating to ounces: Breakfast—coffee, 1; bread, 4; butter, 1; milk, 6; sugar, 1; oatmeal, 1; beefsteak, 6. Dinner—rice soup, 8; bread, 4; roast beef or roast or boiled fowl, 8; potaoes, 8; other vegetables, 6; pickles, 1; bread pudding with sauce, 6; or custard frozen, 8; fresh fruit, 6. Supper—tea, ¼; bread, 6; butter, 1; milk, 2; sugar, 1; cold roast mutton or cold roast beef, 4; stewed dried fruit or baked fresh fruit or apple sauce, 4. The staples—coffee, bread, butter, milk, sugar, and fresh and dried fruit, are the same for each meal, but there is a daily variety in meats and other articles for breakfast, dinner, and supper. The proportions are about the same, however, especially in the matter of meats, as in the specimen diet table given above. In addition to its use for convalescents, the table is now observed for all naval-hospital employees, and is gradually becoming the standard aboard ship and in the marine corps. Its adoption was the result of most patient and thorough investigation by Surgeon I. D. Gatewood, who consulted all the leading authorities on the subject.

A Would-be Suicide.—The following story well illustrates one cause of the prejudice against European physicians that prevails in China. The case was included in Dr. C. C. de Burgh Daly's report on the health of Newchwang. "A most determined attempt at suicide took place on board a British ship. A pantry boy, a native of Ningpo, aged twenty-three years, had a dispute with the steward, and, seizing a small table knife which was well worn down by frequent polishing on a knife board, he entered it on the left side of his throat, and, cutting backward and across, severed the trachea and œsophagus. When I saw him he was not much collapsed; very little bleeding had taken place. The wound was over two inches from side to side, and was very deep in the central line; the trachea, completely severed, was tilted and in a faulty position with relation to the entrance to the larynx. On attempts at drinking, the fluid came out through the wound or passed into the trachea, causing violent fits of coughing. For over sixty hours the patient absolutely refused to allow us to do anything for him, struggling violently and with great strength whenever I attempted to feed him. His one wish was to die quickly, and he implored me to bring about that result by cutting his throat to a greater extent. However, starvation reduced him to a better state of mind, and he expressed a desire to live and be cured. A soft-rubber tube was passed by the mouth every four hours and guided into the lower opening of the œsophagus by a finger in the wound. In spite of a sharp attack of bronchitis he made rapid progress toward recovery, and left here some weeks later on the advent of cold weather, with only a small opening into the trachea and œsophagus. He was given a tube and taught how to pass it for himself. In accounting for the wild and blood-curdling legends about the doings of foreign surgeons and others, which are so prevalent among the natives, it may be of interest to add that this youth, in order to 'save his face' in regard to mutilation of his body by his own hands, gave the following explanation of the occurrence to the comprador and other natives on board the steamer he travelled home in: 'When I arrived in Newchwang I was very ill, and the captain sent me to the foreign doctor, who was unable to cure me, and consequently he [the foreign doctor] cut my throat in order to let out the hot air.'"

Liquid Air in Medicine and Surgery.—The discovery of how to produce liquid air is due to an Englishman, but it is said that an American has gone further than this and has succeeded in putting the discovery to practical use. He also claims that in medicine and surgery its possibilities are numerous. According to the *Cosmopolitan:* "By means of this process, air absolutely free from germs could be furnished in any amount; and if the stimulating effect of an excess of oxygen was desired, it could be had without trouble, quite free from the impurities which now often make this gas objectionable. The temperature of hospital wards, even in the tropics, could readily be cooled to any degree prescribed by the physicians in charge; and by keeping the air about yellow-fever patients down to the frost point, the nurses would be perfectly protected against contagion and the recovery of the patients themselves facilitated. Again, the cauterizing cold which liquid air is capable of producing might be used in cases of cancer with great advantage, as compared with nitrate of silver, since, while it absolutely destroys the flesh to which it is applied, its action is perfectly under control and can be stopped in an instant. It is probable also that hay fever, asthma, and even consumption could be greatly relieved without change of climate by this pure, cool, germless air."

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending July 2, 1898.

SMALL-POX—UNITED STATES.

THE LODGE DOCTOR: HIS ADVENT, HIS METHODS, AND HIS INFLUENCE ON THE PRACTICE OF MEDICINE.

BY THOMAS J. HILLIS, M.D.,
NEW YORK.

Chapter I. Describing an Attempt on His Own Life by a Weary Physician.—A splash in the water and a muffled sound as of a human being in distress reached her ear as she sat at the open door of the cabin at dusk one even in the fall. "Father! father! some one overboard! Quick! quick! I saw the body shoot up! Quick, or you are too late to rescue!" The speaker was the captain's daughter; their bark was in the West India trade, but now riding at anchor near the shore of an unfrequented street in an outlying part of the city. The captain and his daughter were the only occupants now on board, save a Newfoundland dog and a parrot.

The drowning man, for such he proved to be, refused help, waiving the captain off with the words, "Let me die, let me die! and hide my sorrows in these placid waters!" When the unfortunate man, however, was about to sink for the last time, he was seized by the collar of his coat by the Newfoundland dog and fished on board with the grappling-hook of the captain. He was rolled on the deck and the water expressed from his lungs by the continuous efforts of his heroic rescuers, while the faithful Newfoundland remained a silent but intensely interested witness of the scene. At last the vital spark rekindled and the unconscious man began to show signs of life.

There was no police officer a witness of this scene to shout with great officiousness, "Somebody to the rescue while I ring for an ambulance!"—no interference with the humane and intelligent hands which were straining every nerve to bring the unconscious form back to life.

On opening his eyes the stranger found himself in a cozy room, surrounded by a man, a woman, a dog, and a parrot. He was at first disposed to upbraid his rescuers for not permitting him to die, but the kindly faces he saw around him and reassuring words he heard banished all semblance of crimination, and his heart grew full of gratitude and his eyes spoke words of thanks to the noble rescuers of his life. His thanks were more profuse when pressed to accept the hospitality of his hosts and spend the night on shipboard, that he might recuperate from his fatigue and strengthen his resolution to give himself in care of that kind Providence who made them the instrument of His will and the rescuers of a life.

After partaking of a sparing repast and a change of habiliment, the captain and the stranger began a short but earnest conversation. "Stranger, since you have passed the meridian of life and the passions have subsided, love, the greatest incentive to suicide, could not have played an important part in your effort at self-destruction." The stranger, though past middle life, was sinewy and active as a leopard, for youth lingered with him still. Youth often clings with pertinacity to some, and love often finds a citadel in the heart of old age. "Stranger, pray relate the circumstances that drove you to take your own life," said the young hostess with eager interest and a kindly feeling for the old man in the expression of her voice. "The mental condition incidental to suicide must be agonizing, for life is sweet, and the outlook must be dark and portentous before a human being will lay violent hands on himself. Have no fear; you are free from legal interference here, and can with safety unburden your mind. In the morning you can go your way. I am sure my father and I will wish prosperity and happiness to be the companions of your journey. If you have dipped your hands in human blood, or in a moment of passion committed a crime from which your nature revolted, I believe you have paid the penalty already, for the remorse that goads one to suicide is the atonement for the crime." "If you have wronged a woman because she was confiding and weak," said the captain, "the balm for your conscience was to have made reparation and lived, that the world might know there's other than depravity the habitant of the human heart when fired by passion and impelled by opportunity." "Kind host," said the stranger, "I am not a murderer in haste to hide from my crime at the bottom of these turbid waters, nor am I a betrayer or traducer flying from justice to the door of fate; on the contrary, I am the victim of circumstances and the subject of cupidity and malevolence. I trusted a brother implicitly, only to have that trust betrayed. I am by profession a physician. My nature was kind; a tale of woe harrowed my feelings and spurred my heart to generous impulses. I gave to my professional brother, and what I did not give he took without asking, until there was nothing left. He afterward by collusion, subterfuge, and trickery stole my patients until none remained. Impoverished and hungry, I was ashamed to beg; to steal, I could not stoop; to die was my only refuge to stifle my imperious longings and I would have drowned my sorrows, as have other subjects of misfortune, in a watery grave. I was not afraid to die; I am not now. Death is a sanctuary to the weary traveller, a condition of complete repose, a return to mother earth. Of cowards I am not one

> 'Who dreads to the dust returning,
> Who shrinks from the fatal shore.'

"Now, kind hosts, I have answered your questions, but the story of my wrongs is a long one and would wear out your patience were I disposed or permitted to relate it to you."

"From the little you have told," said Miss Post, "your story must be an interesting one. What better way to while away an idle hour than listen to its recital from the victim of such presecution and suffering? My father and I will only be too happy to hear your story; our interest will be keen and our sympathy spontaneous in the misfortunes that seem to have marked you as their own. Proceed, then; the light is bright, the hearth cheerful, and the night young. Ours will be a pleasure mingled with pain."

Chapter II. The Physician Tells why He Determined to Take his Own Life.—The author of

my poverty and predicament, as I have already told you, is none other than a professional brother whom I trusted most implicitly, but he basely betrayed that trust and lost no opportunity to undermine my reputation and cover me with scorn. While he was hanging to the coattails of respectability he assumed a fraternal tenderness that was touching, and begged me to introduce him among my friends, that he might be a beneficiary of the good things they had at their disposal. He called to me while rotating with great velocity at the periphery of the social wheel of fortune to take him to a place of safety near myself at the centre of motion, as he was in peril of falling from the outer rim and being precipitated into space. After being pulled to a place of safety and at great risk to myself, his gratitude took the form of an endeavor to pitch me out into the unknown, that he might navigate the aerial car for his pleasure and benefit.

After this dastardly act he somehow managed to ingratiate himself again in my favor, and subsequently he was taken on board of my yacht as a guest, when immediately he hatched a conspiracy to murder me and scuttle the ship. I left my practice in his care, to take a few days of much needed rest in the country. On my return I found chaos at home, and every step I took to ascertain the cause developed the fact that he was ceaseless in his efforts to supplant me in the esteem and affection of my patients. Previous to this, as a cure for my dyspepsia I went to the continent, sightseeing for two months. While abroad he was anxious about my health, and particular that I should visit Switzerland. He wrote:

"Dear Dr. Gee: It gave me inexpressible pleasure to read your letter just received. I feel now assured that your recovery will be only a matter of a few weeks. Since your dyspepsia has already disappeared, the other symptoms will vanish, too, in the rarefied atmosphere of beautiful Switzerland—a country you must be sure to visit; explore the glaciers and climb the mountains of that picturesque land. Climb high; you have an opportunity now to inscribe your name on the roll of fame. Opportunity seldom comes twice in a lifetime. Catch the tide at the flood."

While writing in this most friendly tone, the wish undoubtedly was near his heart that I should perish in that foolhardy attempt, be precipitated from an overhanging peak or surprised by some yawning gulch, lie deep in a mountain ravine forever buried in a mantle of snow, and this inscription on my tomb—the mountain desert:

"Went tumbling down the torrent of his fate."

With what diabolical glee he would rub his hands and what hypocritical cant he would display in relating with tears the tragedy of my death to those stricken with sorrow at my untimely end!

"Dr. Gee, beg pardon for interrupting you at the outset of your story," said Captain Post; "but might I ask you for the name of this monster who so basely betrayed his benefactor? He can hardly be human." "No, no, papa, he is a fiend!" exclaimed Miss Post, with spirit in her manner, and defiance and hate for the author of the old man's misfortunes glaring in her blue eyes. "He is a man, a physician; by name Dr. Quick, the medical director of the Knights of the Golden Rod," said the stranger. "A man, a knight, and a director," said the captain with amazement. "He is out of place here. He should be a director below." "Yes, papa, that region is the most appropriate place for his peculiar talent." "There he would find boundless opportunities for hatching conspiracies and an able coadjutor in his master, the devil," added the irate captain. "Describe him, describe him," said the captain and his daughter with one voice; "we will not interrupt you again, Dr. Gee, so proceed with your story."

This man is not a medical outcast nor is he a quack in the ordinary acceptation of that term, said Dr. Gee. However, he is more dangerous on that account. If a leper is branded as such, the community will have an opportunity to shun him; but if that leper touches up his scarred and sodden face and decorates himself in fashion, he will for a time escape detection until the effluvia from his hidden sores begin to penetrate the olfactories. Then there are an inquiry, a surprise, and a stampede, and a relegation of the offender to the companionship of his kind or to a lonely solitude. The other leper sometimes wears his disguise for an indefinite time. As a rule, he dresses well, even if he has to procure his clothing on the instalment plan, which he often does to the sorrow and disgust of the confiding tradesman; as his (the leper's) pachydermis is thick, he can stand an extraordinary amount of dunning and he ultimately succeeds in wearing out the patience of the unfortunate tailor. At the outset of his career this lodge doctor is seized with an inordinate and atrocious ambition, namely, to be successful, even if disaster and ruin to his brother practitioner be the price of that success. I by long and arduous labor in the field of honest endeavor succeeded in surrounding myself with an appreciative and remunerative *clientèle*. The purpose of this man was to pull down the structure I built, that benefit might the more speedily accrue to himself from the destruction and spoliation of me, his benefactor. He aimed to reach the land of promise, a land flowing with milk and honey, by the back door. By the legitimate practitioner this land is reached only by a long and straight road, where censors to examine his passport and judge of his fitness are stationed at intervals.

This lodge doctor has a horror of this road. He will not enter on it; it is too long; the task imposed there is too arduous. He might break down on the journey or be turned back by a censor as one unfitted to proceed; besides, his passport might prove a counterfeit. In such dire contingency he would incur the displeasure of the censor and be in danger of deportation or death. To avoid such formalities he has resolved to enter by a back door and through a bypath leading through a swamp. The sign, "No admittance here," has no meaning for him, and under cover of darkness he undertakes the journey. The distance to be traversed is short but abounds in underbrush and stinkweed, with numerous marshes giving out malodors and reeking with germs of nameless diseases. He emerges from this swamp covered with slime, and with the temerity and demureness of a burglar who has successfully blown open a safe and escaped with the money drawer. On his belly he crawls; he finds an avenue to the door, through which he stealthily creeps into the ranks of the worthy, who have presented their passports and won their spurs by honest endeavor.

This Dr. Quick, a knight of the Golden Rod, is a soldier of fortune who accomplishes deeds of daring with his tongue and who fights best when there are rations in sight. He attaches himself to the commissary train, and can always be found in the storeroom or larder, a position in which he fortifies himself so strongly that only a bayonet can drive him to the open. His eyes are on booty; he will carry it away if he can, having no scruple to see the rank and file of the army go hungry or die of exhaustion from lack of that food he has pilfered and sold to the enemy.

Chapter III. The Reign of the Lodge and the Sand-Lots Orator. His Advent.—Before the civil war little was known of the lodge doctor. True, he had a vicarious existence, but was seldom heard of

by the general public; now, however, he is very much in evidence and lodge doctors are as plentiful as mosquitoes on the Hackensack meadows in sultry August weather. During the last few years societies have organized and increased with great rapidity. Workingmen and mechanics, believing that their interests lay in a closer union, banded themselves together into clubs, courts, and circles—various names to designate the same thing, but under whatever name their purpose is always the same. These bodies of laborers, artisans, and mechanics have full lists of officers from president down to the negro camp follower. Obscure among these officers is the lodge doctor, who in a number of instances must be a member of the circle over which he has the honor to preside as medical director. Some of these lodges are close corporations, and often are run as much in the interest of the presiding officers as in that of the rank and file of the order.

The tendency of the hour to form combines and trusts is not by any means confined to the bloated bondholder and capitalist. Those various lodges are simply little trusts scattered over every city and town in the United States, and are about as plentiful as polling-booths throughout election districts. A large proportion of those societies have medical officers; sometimes two or three societies club their interests and have one between them. Seldom, however, is this necessary, as doctors are so plentiful, especially poor ones, that their services can be had for a pittance—yes, the merest pittance. It will be shown later when I come to consider the methods of the lodge doctor, that he accepts this pittance in the hope of making acquaintances among the lodge members and their families, which will recompense him for the small stipend he receives from the lodge. These lodges, while very careful that their own interest be protected, that all comprising their unions have the full benefit of their advantages, are ever ready to take advantage of a weak spot in other industries, and offer the smallest possible remuneration for the greatest possible amount of labor. They are ever ready to denounce one of their own members who steps into a breach to work for smaller wages than he who was previously employed, while they are always on the watch to procure cheap labor themselves in the way of a medical adviser at a disgracefully low price—as a fee a few cents per visit. It is the habit of these lodges to denounce capitalists and regard them as their arch enemies; but every member of a lodge has an ambition to be himself a capitalist. This ambition once satisfied, he often domineers over the less fortunate, whom he distanced in the race. They make incursions into the higher intellectual pursuits to tempt the medical weakling and persuade him to be a scab, though that name is despised, proscribed, and covered with opprobrium by every mother's son of themselves. Their bylaws denounce him as a traitor, as do their orators inside and outside their halls.

These lodges need councillors to keep them from illegal transactions, physicians to keep up their standard of health, and clergymen to remind them of a hereafter, to prepare them for the exordium by pointing the way. They, however, secure the services of only the inexperienced and raw recruits, old soldiers refusing to enlist under their banner or serve in their ranks, as the equivalent for such services is on promissory note rather than cash on delivery. It will be noted that these champions of labor are not willing to grant to others the rights and privileges they claim for themselves, and enjoy undisturbed. They procure the services of a lodge doctor at the lowest possible figure, and often barter for months and close the sale by knocking the medical directorship down to the lowest bidder, regardless of qualification or other attribute. They secure the cheapest talent in the market; they get just what they paid for.

A man wants a cheap coat. He will not go to a Fifth Avenue clothier to obtain it, but will find his way to the Bowery or Chatham Street; there he will get just what he wants—a cheap coat. He is not willing to pay for a trustworthy, reliable garment, so he has to take shoddy, and no man who sees him wear it is deceived in the quality of the goods. The lodge was dickering and bartering for months, playing one unfortunate physician against another, when finally they took the cheapest, and after some formalities installed him as medical director and guardian of their lodge. They wanted a cheap man and they got him. As in the case of the clothing, judges will not be deceived by the feel and cut of his professional efforts.

The crucible of the social alchemist is bubbling; the heterogeneous mass is breaking up and entering into new combinations; these combinations are crystallizing into courts, circles, lodges, and clubs.

The transition period is not quite complete, for they are still hot and vapory, and it will not be before the perfect arrangement of their atomic equivalence, which in workingmen's lodges should mean fair dealings with others as well as between themselves. As I speak, the orators of their social propaganda are shouting from the sand lots and declaiming from work benches to their auditors, the people, the advantages to be derived from the workingman's lodge and the special blessing it bestows on him by associating himself with them. "Only be one of us," say they, "and you will have all of the necessaries and many of the luxuries of life at retail for wholesale price. Your family physician charges you from $1 to $2 a visit for professional services. We can give you these services by contract at from 5 cents to 25 cents a visit. The doctor on your block charges $3 for a night call; we can send you our lodge doctor, who will do the same work for 25 cents, and who will get out of bed at the tap of the bell to answer your summons. We have ways and means for doing things cheaply, since we retail at wholesale prices. This is only one of the many advantages we offer to you, as, for instance, $5 per week as a sick benefit, free drugs, and free burial, and if you are conspicuous among us—that is, if your talent soars above by making revolutionary speeches and denouncing capital—we will fill the papers with a glowing obituary of your worth and our sorrow, and erect a monument to perpetuate your memory." So determined and persistent have been the apostles of this gospel of socialism in private and public, in season and out of season, that their converts are as numerous as the sands of the sea, and workingmen's lodges as plentiful as strawberries in June. The whole union is one vast camp of workingmen's orders, known by hundreds of names, as suits the taste or fancy of the organizers. The lodge doctor has a place in this great army; it is not an honorary but a numerical one, and he has often to dance to poor music and bite the dust to please the hardest of all task masters, the laboring man suddenly thrust into power. The old adage, "Put a beggar on horseback," etc., has its exemplification here in the abuse of opportunity and the vindictive and cowardly spirit shown to the helpless and dependent under his control.

The mania for the formation of societies and lodges has had a steady growth for thirty years. From the national guard of the State to the chowder club in the ward, the same spirit is manifest, namely, a hankering after martial glory and a kind of independent, self-sustaining spirit. The habit for combination has become so popular that wherever a workingman is found there is a lodge or society man of some sort or description; if he is not, he was approached

and refused to be one for some conscientious or other reason Even women and children are deemed fit material for their designs, and are being drummed into the lodges of these socialists to be beneficiaries in common with the male members. The ladies' honorary lodges of this or that order and the children's lodges are common phrases nowadays. The whole fabric of society is honeycombed with these lodges and circles, and if the excavations continue the end cannot be far off; that end will be chaos and social anarchy and finally ultimate ruin to the workingman himself, since he cannot logically expect better treatment from the capitalist whom he denounces than he is willing to mete out to his own subordinates and others over whom he has a temporary control. It is the fear of a cataclysm like this overtaking the masses that has led certain ecclesiastical authorities to view with alarm and watch with suspicion and apprehension the rapid progress made by these cabals or courts in welding the masses into one socialistic co-operative union, that may be at any time wielded as a power for evil by an unscrupulous and ambitious leader. Whether the leading spirits of these societies are animated by selfish, ulterior, and sinister motives, or inspired by humane and enlightened impulses, is a proposition presented for solution to him who comes later on the scene. In passing, however, a question may be asked: How much benefit does the workingman derive from his club or society? Is the rapid spread of the lodge and the court a harbinger of better times for the masses? Will the good accruing to them outweigh the personal freedom surrendered and the tearing asunder of social ties incidental and inevitable to the slavish obedience imposed by their order? This question, I repeat, with its many sides and various aspects, is respectfully submitted to the sociologist and student at work in the field of human endeavor.

Chapter IV. The Weapons the Lodge Doctor Uses to Accomplish his Purpose. His Methods.—It is in his methods that the lodge doctor stands out conspicuously and excels all others. In the lodge he has a field suitable for his peculiar talent, and he works this field with an ardor and vigilance that command attention if not respect. As his reflexes do not respond rapidly and his circulation is torpid, he does not mind the snubs and kicks he occasionally receives when forcing his professional attentions in unappreciative quarters. He is, however, not unconscious of these marks of esteem, but considers it neither wise nor expedient to war on conditions which may enhance his financial status at some future period, though confessedly detracting from his personal and professional estimate by the impartial observer of all the circumstances involved in the curious case. This physician bows with seeming alacrity to circumstances he is powerless to avert or control, and stoops to conquer.

It is really amusing to watch one of these fellows courting popularity and the devices adopted to make his presence known to the denizens of his bailiwick on a pleasant summer morning or afternoon, while taking his casual but well-considered stroll as he mechanically glides along the flagged walk. With eyes turning at once to all points of the compass, and with the rapidity of thought rotating around his cranium, he sees friends, real or imaginary, craning their necks to meet his smile half-way. It may, perchance be in a doorway, at a window, or by a basement gate. His sight is keen and discerning, and at the slightest sign of recognition his face is aglow with a radiant smile, and pleasurable sensations, like forked lightning, shoot up and down from his head to his heels through his spinal arch and through space to greet his appreciative and new-found friends. Then commence the hat evolutions and the good-natured grimaces, the obsequious bowing and nodding and swaying of the body, like a dervish at prayer. No circus clown, contortionist, or Hindoo juggler could begin to be in it with this acrobatic artist of the sidewalk and Knight of the Golden Rod. So rapid are his motions and so continuous his efforts that he is in peril of his life from sudden disarticulation of the atlas or fracture of the odontoid process of the axis. This gentleman aims to catch the public eye by expertness in bowing, nodding, and dodging with limitless area of smile and the hat trick developed to a fine art. His method in this respect differs widely from that of his advertising brother, commonly known as quack; his manner of operating is in marked contrast to the latter's. The quack appeals to his constituency through the press: outside of it he is as impersonal as the hospital doctor or a Parsee deity; he wraps himself in a mantle of mystery and prefers the people to know him as one who works miracles through his communion with nature; that he seeks her in the solitude of the wilderness, follows her through the shadow of darkness and into the bowels of the earth, and there importunes, implores, beseeches her to impart to him the power so potent with her over health and disease and the lives and destinies of men, that he may go back in triumph to his forum, and from the rostrum of its columns shout aloud to the maimed and the sick to come and be healed.

Now, through the instrumentality and judicious use of the lodge Dr. Quick is about to accomplish a remarkable feat, and that in an incredibly short space of time too. He knows that other physicians in his neighborhood have worked for years with a tireless industry to establish themselves in practice, and often without success. He wants to be wholly successful, and quickly at that, as he is anxious to show these laggard physicians what a hustler can do; and herewith he accepts the honor of being medical adviser to the order of the Knights of the Golden Rod. This honor, by the way, was up at auction for six months waiting for the lowest bidder; so it was knocked down to Dr. Quick, since he underbid all competitors. As the remuneration was small and the terms incidental to its acceptance were so contemptible and humiliating that none of his neighbor physicians cared to be in any way identified with it, Dr. Quick jumped at this opportunity; in the lodge he saw a weapon with which to strike his professional brothers and further a means to emancipate himself from the clutches of the bailiff who had him in the toils for numerous board bills he was careless about paying, and tailoring on the instalment plan, the contract obligation for which he refused to comply with, though he loved to exhibit himself in the latest style and put himself on exhibition at an hour when beauty and fashion were wont to patronize the thoroughfare.

After thirty years of active practice I surrounded myself with a remunerative *clientèle;* now Dr. Quick has pulled me down and built on my ruined reputation a fortune in five years. It will now, my dear friends, be my task to tell you of the methods by which Dr. Quick accomplished this remarkable work.

In the beginning Dr. Quick was careful as to the means to be employed in laying the foundation of his fortune. He did not advertise in the papers or pay a thing in fantastic regalia to distribute hand bills on the avenue; that sort of thing had too much the odor of the quack. He has no objection, however, when the lodge members extol him, and sound aloud his praise, and give a wide publicity to his feats in surgery and his skill in the art of healing. It pleased him immensely, when some enthusiastic lodge brother whispered in the ear of the enterprising reporter, that he might be able next morning to read with rapture of himself. There it could be seen by all, not as a vul-

gar advertisement but as a thing accomplished—a fact, a triumph, a successful operation on a town councillor at midnight. It was a difficult and dangerous operation, but the skill and nerve of Dr. Daniel Webster Quick, medical director of the Knights of the Golden Rod and consulting surgeon to the sister lodge of the Magic Circle, were equal to the occasion. His skill and pluck at that supreme moment snatched victory from defeat. Other physicians tried this operation before and failed, but it was reserved for Dr. Quick to be the pioneer and for the lucky councilman to be the subject of his success. In the manner of his methods, as was before touched on, Dr. Quick differs widely from the symptom-blank man, who generally works in the light and above board. Dr. Quick toils with ingenuity in the night when the members are mellow after the hop, when the fluids in the refreshment cabinet run dry. At this happy period there are a thawing and a melting away of formalities and an interchange of confidences worthy of the physician and his voluble and versatile constituency of the lodge.

The First Step toward the Accomplishment of his Purpose.—Dr. Quick makes it a point to appear radiant and resplendent at the oft-repeated reunions of the lodge, and always by one means or another manages to make himself conspicuous and to be the centre of attraction, sometimes by the singing of a song, at other times by the recitation of some patriotic exploit. If the American element is dominant in the crowd, it will love to hear the "Star Spangled Banner" or the "Sword of Bunker Hill," and the valor of Old Put will fire the martial heart. If the majority be of Teutonic origin, the "Watch on the Rhine" is very apt to rouse the fire dormant in their sluggish blood. If the Celt is the major element, "The Wearing of the Green" or "The Harp that Once through Tara's Halls the Soul of Music Shed" will cover Dr. Quick with glory and transform him into their household idol for many moons. If some member is absent from one of those reunions, Dr. Quick is thoughtful. Next day he will make it convenient, but in an easy and indifferent manner, to call on the member. He is not fearful of an accident, though all may not be well; however, he only dropped in casually as he was passing by. He looks affectionately on the children, asks if Santa Claus was around at Christmas; and if so, what he brought to the twins, who, he is certain, look wonderfully like their father, the worthy vice-president of the lodge, though he sees the eyes and nose of their mother, Mrs. Tubbs. "Strange blending of two in one," quoth the doctor in an undertone of reflection. "Are they vaccinated, Mrs. Tubbs?" She declared they were, three months previously, by Dr. Butts, her family physician. "Mrs. Tubbs, would it be too much to ask you, have you a yearly contract with Dr. Butts the same as I have with the knights of the lodge of the Golden Rod, or perhaps you pay him by the visit? In that case medical attendance comes high, as those old-fashioned physicians attach great value to their services. It is often my duty, Mrs. Tubbs, a disagreeable one, I assure you, madam, to point out their faults and remedy the blunders they are continually making in sick-rooms. It is not an uncommon thing for them to mistake one disease for another, but, Mrs. Tubbs, those fellows never mistake a five for a ten-dollar bill when being paid for services they but poorly rendered."

"As you asked I will tell you. Dr. Butts was my mother's doctor and he has been in our family since my marriage to Joshua Tubbs, now nearly ten years since." "Yes, Mrs. Tubbs, I nearly forgot. Vice-President Tubbs has asked me to be his guest and recite a piece at your wooden wedding next Monday night. I am sure the invitation has your indorsement." "Indeed, it has; we will be only too happy to have the pleasure of your company on that occasion, my dear doctor," said Mrs. Tubbs. "My husband has repeatedly told me you were excellent company and the soul and life of a party. Why, we will be delighted with your presence. Why not bring a nice young lady of your acquaintance, or, Dr. Quick, if you don't mind, I will introduce you to my niece. She came out last spring and was received with enthusiasm by the society folks of this town. Yes, Dr. Quick, Eveline Tubbs was an immediate and unqualified success—stately in presence and of unusual accomplishments. She is sought after and admired by all." Dr. Quick: "It will give me great pleasure to meet Miss Tubbs on Monday night, and allow me, Mrs. Tubbs, to express my sense of gratitude for your thoughtfulness and concern about me."

Just as Dr. Quick was about to take leave, Mrs. Yep, wife of the sergeant-at-arms, entered. She was a mutual friend and well known to Dr. Quick and Mrs. Tubbs. She was excited; she came to tell of a calamity that had happened in the Quigg family. Poor Mrs. Quigg had expired only an hour ago! The announcement of her death fell like a thunderbolt on her numerous friends. It was too bad that such misfortune should visit the household of the janitor of the lodge. Dreadful! Just think, only two months ago he lost his only boy, George Washington Quigg, and now his good wife! Yes, awful to contemplate! Four little girls, too, are left to mourn their loss by the premature taking off of a devoted and affectionate mother. "Mrs. Yep, what could have caused the sad event?" said Mrs. Tubbs; "why, I saw her at church last Sunday." "You took the word out of my mouth, Mrs. Tubbs. I was just going to tell you all about the unfortunate affair—blood poisoning; yes, blood poisoning, that was what it was, Mrs. Tubbs." As the words "blood poisoning" died away on the lips of Mrs. Yep, Mrs. Tubbs raised her eyes heavenward imploringly, while a chill crept over her body. Had not a lady, a dear friend of hers, died of that dreadful disease? "Oh, Mrs. Yep, the thought of that tragedy makes me shiver! It was Dr. Fly, Dr. Quick's assistant, we first blamed for it. I was there when Dr. Butts was sent for, to ascertain, if possible, the cause of the delirium and high fever, by her brother, my husband, Mr. Tubbs, vice-president of the Knights of the Golden Rod, who, as you know, places the most implicit confidence in you, Dr. Quick." "Ladies, Mrs. Tubbs and Mrs. Yep, it was my duty to ascertain the cause and place the blame where it belonged, just on the shoulders of Dr. Butts; yes, I had to do my duty, regardless of whom the lightning struck. My assistant was blameless, and had the family been wise enough to continue his services in place of calling in old Dr. Butts the result would have been different. Dr. Fly telephoned me that the family on the third day after the miscarriage substituted some one else for him, and that he was dismissed from the case. In such a contingency and a question of professional honor affecting my worthy assistant, Dr. Fly, there was no alternative left for me but hurry from the mountains, where I left the president of the Union Trust Company, who was suffering from angina pectoris, in care of my assistants, to investigate and ascertain the facts in this case, and relieve if possible Mrs. Topsy, the sister of my worthy brother, the vice-president of the Order of the Golden Rod. Poor woman, though I travelled by express, she expired twelve hours before I reached her bedside. I will admit Dr. Butts saw her only once, three hours before she died, but on that occasion he injected something under her skin. Now the question is, what was that something? There was only one way to find out, and that was a coroner, an inquest, and a rigid investigation. I shudder myself from the consequences that would befall Dr. Butts if such an in-

vestigation were permitted to proceed. I advised my worthy brother, Vice-President Tubbs, to let the matter drop, as investigations were powerless to bring back the dead, but they could harrow feelings already lacerated and make a lot of trouble for Dr. Butts. I advised that the matter should be dropped, and Dr. Butts left to settle the affair with his own conscience. I feel now, as I felt then, that the sting of remorse is the greatest punishment to inflict on a human being. Poor Butts, how he must have suffered."

Chapter V. Dr. Quick is Repulsed, it Being a Setback to the Conspirators.—When Dr. Quick entered the door he felt rather sorry for coming, but since he had made an engagement with Mrs. Muggy to meet her at the house of Mrs. Lutts, he then had no option in the matter. The ladies were talking in an animated and bellicose tone. It was on the subject of the relative merits of their respective physicians. Mrs. Muggy had promised Dr. Quick the day before that she would win Mrs. Lutts over to him, and that at her next lying-in he would be substituted for that crusty and haughty old chap, Dr. Gee, whom she hated. Dr. Quick had only a speaking-acquaintance with Mrs. Lutts, as her husband, Trustee Lutts, was only a recent recruit and brother lodge member of the worthy Knights of the Golden Rod. In Mrs. Muggy, however, he had a powerful and influential friend; she could sway all and manipulate at her sweet will, and often had she turned defeat to victory. She was, however, rather astonished to meet such opposition in Mrs. Lutts, who fought like a fury for her old physician, Dr. Gee, who she admitted was proud and old fashioned; though he had been her physician for eight years he had called only once without a professional summons, and on that occasion it was while attending her neighbor next door, a lady suffering from melancholia. "Don't you know, Mrs. Muggy," said Mrs. Lutts, "that over-familiarity detracts from a physician's respect and otherwise impairs his usefulness?" "Oh, yes," said Dr. Quick, taking up the remark dryly; "there is an old saying that 'familiarity breeds contempt,' but I presume, Mrs. Lutts, I know when and where to be familiar, and believe I have not overstepped the bounds of gentlemanly reserve and good breeding in making a passing unconventional call on the wife of a member of the knights of our ancient order. It is the doxology of our creed to cultivate a spirit of kindly relation and mutual good fellowship between each other and between our families; to a knight of our order the family circle of his brother knight is a retreat from care and a home of relaxation and repose. We respect social obligations, and the family relation to us is supposed to be as the apple of one's eye, a relation to be guarded with a jealous care."

"Dr. Quick, I fear you have misunderstood me and misconstrued my words; I had no intention to be personal when I mentioned some of the characteristics of Dr. Gee," said Mrs. Lutts, who continued: "I may cause you some disappointment and very possibly may make an enemy of Mrs. Muggy when I say that I am perfectly satisfied with my old physician, Dr. Gee. The arguments by which Mrs. Muggy endeavored to prove his incapacity were offensive and distasteful to me, and only raised him higher in my estimation." Mrs. Muggy chafed under the setback she received from Mrs. Lutts, not so much for herself, she said, as for that college-bred gentleman, Dr. Quick, whom everybody but that Lutts woman loved to honor. It was outrageous to offend him to his face—the kind, good, dear man. She would go and see her other friend, Mrs. Tripp, who expected to be confined in a few weeks. She would have no trouble there; that case would be a sure thing for Dr. Quick, and it would be rather a surprise for him to know that she had interested herself again, for she had said, after the insult Mrs. Lutts had given her, that she would quit further introductions and canvassing; in short, that she would leave off prospecting altogether, but would continue her kindly relations with and good will for Dr. Quick.

Mrs. Muggy was not any more surprised than was Dr. Quick, when she entered Mrs. Tripp's parlor, to find Dr. Quick playing with old Gip, Mrs. Tripp's pet dog. He had understood that Mrs. Tripp was about to be confined, from a hint dropped by ex-President Tripp of a kindred lodge, the Knights of the Magic Circle, and had only dropped in just as he was passing the door. He inquired what fee she had paid Dr. Gee for his services in her previous cases and whether she intended to have him in this, her approaching accouchement. "I have had him engaged for the last two months," said Mrs. Tripp. "You know Dr. Gee is a stickler for etiquette, and would not attend even me, whom he knows so well, without that necessary formality." "Pity about the old chap," broke in Mrs. Muggy, who was an intensely interested listener to the conversation. "Dr. Quick, won't you tell Mrs. Tripp about that dreadful Mt. Carmel case; it makes beads of perspiration stand out upon my forehead when I think of it. Indeed, it is the most horrible case I ever heard of." "No, you tell it, Mrs. Muggy," said the doctor, "as you are better acquainted with its early history than I. You are perfectly right though, Mrs. Muggy, it was a most sad case. Kindly make the recital as brief as you can, as I have an operation to perform on Bishop Soule at four o'clock. My four assistants will be waiting; it is now three." "Well, she lived in Mt. Carmel," began Mrs. Muggy. "She was Vice-President Call's sister of the Circle of the Harvest Moon; she was a near relative of Vice-President Tubbs' wife. Just on the ninth day after her confinement, and three hours after Dr. Gee left with his fat fee of $25 in his pocket, averring as he went that all was well and that Mrs. Rocks could sit up next day, poor woman! she was seized with a chill and a dreadful spasm convulsed her frame. She frothed at the mouth and kicked and bit like a person afflicted with hydrophobia. Poor woman; I feel overcome. It almost makes my heart stop. I had to run at midnight for Dr. Quick, as her good husband, the major-domo of the Golden Rod, was ill upstairs. It is surmised that he ruptured a blood-vessel in an effort to throw a heavy hammer sixty yards. Poor man, it fell on his toes. Since then he has been a cripple. At this crisis in the affair, of course we naturally lost confidence in Dr. Gee, who lives near by. I ran quite a distance to summon Dr. Quick, and by good luck he was at home and immediately accompanied me to the sick-room. Poor Mrs. Rocks, it was pitiable to see her, but noble to witness the effort poor Rocks made to limp downstairs when apprised of her danger, and to see him wipe the beads of perspiration from his good wife's brow and kiss her florid cheeks. Mrs. Tripp, I am growing faint with the realization of this horrid drama; won't you finish the dreadful story for me, Dr. Quick, as I am overcome with emotion and feel dizzy in the head." Dr. Quick: "Anything to oblige you, Mrs. Muggy. To begin, between spasms she had strange delusions and weird fancies; she thought Dr. Gee was a goblin and about to devour her child; again, she thought he was a child snatcher, and made desperate efforts to prevent him from laying violent hands on her boy, who was reposing quietly in his crib. The frenzied woman—it was very trying to be a witness of her despair, but beautiful to see the effort she put forth to save her child from the designs of Dr. Gee. After this episode Dr. Gee's name grew hateful, and I thought it expedient to caution those about to abstain from using that name at all, as every time the patient heard it uttered it was only to bring on another attack, more dreadful than the previous one. As the ladies

in the sick-room were showering on Dr. Gee epithets not of a complimentary nature, because of the condition in which he left the sister of the most worthy vice-president of the Harvest Moon Lodge, I told them not to blame him too much; that perhaps Dr. Gee did all in his power for Mrs. Rocks; but that there was a probability that he did not understand or recognize the symptoms of the coming nerve storm when he left her house three hours before. In that case, I did not think it fair to blame him for a condition of which he had no knowledge; against him, however, was the fact that he undertook to accomplish a something that was beyond his ability, with almost disastrous results to the accomplished wife of the major-domo of the Golden Rod, who himself unhappily was ill at this particular juncture, suffering from the bursting of a blood-vessel and fracture of a tarsus from the accidental falling of a heavy hammer. Yes, good ladies, I said that Dr. Gee, in the spirit of a selfish pigheadedness that is born of ignorance and arrogance, undertook a task for which he was by nature and training wholly unfitted; as before said, to the detriment and injury of that interesting and once happy little family about whom we were so alarmed just then. My advice was to move cautiously in the matter and leave him severely alone, as Dr. Gee was operating at great risk to his own reputation, as well as to the life of Mrs. Rocks. I told them that there was a retribution for him, from which he would be as unable to escape as was Dr. Butts from the dreadful blunder he made in taking the life of Master of Ceremonies Janitor Quigg's wife of the Order of the Golden Rod. Yes, there is a retribution, a reckoning for all, and when that day comes it will be a dreadful one for Dr. Gee as well as Dr. Butts. I said that by following this advice Dr. Gee would escape the shame of being dragged into a police court, and I the mortification of having to appear as a witness against a brother physician."

Dr. Quick neglected to add, as he was in a hurry to operate on the bishop, that it was hinted by some cruel gossips that Mrs. Rocks was running the beer can pretty lively that evening for the accommodation of the numerous lady friends who called on her after Dr. Gee left, to see who the baby looked like and if he had a dimple in his chin; poor Rocks upstairs, unconscious of the revelry below, was nursing injuries sustained by a foolhardy attempt to exploit himself with athletes of high muscular development, while he was only a mass of adipose tissue.

There might have been a grain of truth in these cruel rumors concerning Mrs. Rocks' doings on that memorable night, since it was certain that she had had some previous attacks of a like character and under convivial but not parturient conditions.

Chapter VI. A Confab between Lodge Chums.—"I declare, you are on foot early, Dr. Quick; you caught the spirit of the old proverb, that 'the early bird catches the worm.'" "Yes, Brother Sparks, I sat up all night to catch the bird, not the worm, and the little chap weighed ten pounds and fifteen grains. Mrs. Tripp was delivered of a boy just two hours ago, and, Sparks, I am going to surprise you. Don't say a word, but it was baptized immediately and called after you—yes, after you—Jeremiah Sparks Tripp. You know, your uncle was Mrs. Tripp's godfather, and one good turn deserves another. Sparks, old boy, they paid you a high compliment, but not one too high for the luminary and leading spirit of the good knights of the Golden Rod." "Come, come, Dr. Quick, none of your flattery," said Mr. Sparks. "I cannot stand it on an empty stomach and so early in the morning. Indeed, I did not wet my whistle yet—I mean I did not have a drink to take the cobwebs off my heart yet, as you know I am doing the mission at the Holy Cross." "Yes, Brother Sparks, I was pleased to hear it from Mr. Jung, the armor bearer of our lodge, yesterday. It will be an excellent example for all of us to follow; don't you know I intend to do the mission myself next week?" said Dr. Quick. "Look here, tell me, doctor, why they hurried up that christening," said Mr. Sparks, with a look of curiosity and merriment in his eye. "Well, it was in this way, Brother Sparks; it was a long labor and a short cord; as the infant was in peril of being asphyxiated, I thought it expedient to give him private baptism." "Did you drink his health, Dr. Quick?" said Mr. Sparks again, with a twinkle in his eye; "I infer so, as you are so jocund and happy." "Quit your fooling, Sparks; you know I am a temperance man for the last two weeks, since I fell down that three flights of stairs at McCarthy's christening. You know he is a worthy knight of the Magic Circle. Good morning, Brother Sparks; you will be at the lodge meeting to-night for the election of a trustee to fill the place of our late lamented Brother Muldowney." "I'll be there, Dr. Quick." "Good-by, Brother Sparks. Just wait a minute, Sparks; I have a favor to ask of you this evening, and I hope you will grant it." "I'll grant you anything, doctor."

Dr. Quick was the picture of happiness as he tripped lightly over the flagged walk, while the creaking of his new russet shoes made music in his ears. Why shouldn't he be happy—his life a series of triumphs and his heart overflowing with happy anticipations?

The Confab Continued after Midnight.—After the meeting to fill the place left vacant by the defunct Muldowney, President Sparks and Dr. Quick retired to the refreshment rooms downstairs—the café of the Golden Rod. Mr. Sparks and Dr. Quick sat at a small table in the distance, out of earshot of the crowd. After doing justice to the goodly spread, in which pickled pigs' feet played an important part, and washing down the repast with generous mugs of new ale, the two gentlemen grew confidential; as more ale was absorbed, they grew still more confidential, until finally the molecular particles of the finer ether filling the interstices of their cerebral spaces began to vibrate and bring them into still closer communion; now their lives mingle, and the lodge brothers, as if free from the encumbrances of physical environments, fly into each other's confidences—two lives as one—a brotherhood of mutual love.

"Jerry, you recollect I said this morning I had a favor to ask of you after the lodge meeting this evening." "I remember it well, Dan; what is it?" "It is this, Jerry. Your good wife Sarah could do me a good turn if she felt so inclined; indeed, she could fill my office with patients and my ledger with influential names. Could you not bring some influence to bear on her in my behalf? She seems not to take kindly to me, and that of no fault of mine, Jerry, as I left no stone unturned to win her from her idol. I pointed out the stupidity of old Dr. Gee, told her of the advantages she would derive if I was her family physician, mentioned the saving to you, Jerry, of at least $100 a year—yes, every year—and that is an item, I tell you, these hard times, don't you think so, Jerry?" "Dan, I explained all this over and over again to Sarah, but it seems to me that old Dr. Gee has hypnotized the poor woman. I don't like his eyes, Dan; there is a strange light in them, and he often makes passes with his hands, just as if he was giving the sign of his order—no doubt a diabolical one—to some elf or goblin unseen by our eyes, Dan, but perfectly visible to his." "Jerry, won't you speak again to Sarah?" "I will, Dan." "You know, Jerry, I never went back on you yet. Recollect last winter when you had the pneumonia, and in the spring when you had that terrible attack of peritonitis, and this fall that frightful attack of typhoid; Jerry, during all that time I stood right by you, always making it a point that your sick benefit

came to the house every Tuesday. If the treasurer did not bring it, I brought it myself, to make sure that you got it." "Dan, I am not unmindful of your many kindnesses; you know it was my vote saved you in committee, or else you would be courtmartialed for attending the picnic without displaying the emblem of our order at our reunion with the Magic Circle." "Jerry, I never forgot that act. How you waited until the other fellows tired themselves out shouting for my resignation, my impeachment—in fact, for my blood. You turned the tide, Jerry, by a master stroke, one worthy the hand of a Richelieu—yes, Jerry, you saved my skin that time; now, Jerry, I want you to be as successful in winning over Sarah as you were in defeating the designs of my enemies." "Dan, rest easy; me you have always, but the names of Sarah and Evangeline will be on your books before the robins nest again; further, I will make it a point that you will be the medical adviser of the whole Sparks family before six months from this night, and every friend of theirs they can influence. Dan, why have you grown sad? Have you got a sting from that old neuralgia again, or is it a toothache?" "No, Jerry; it is a heartache. Thoughts of other days crowd upon me and envelope me in an atmosphere of gloom. Jerry, when I am overtaken with these strange fancies I am afraid of myself. I want to take refuge somewhere out of my own existence." "What other refuge for you, Dan, than the bosom of your tried and true friend, Jeremiah Sparks, of Sparksville." "Jerry, my confidence is well placed and my refuge sure." "Dan, cheer up and tell me what made you sad." "Jerry, don't ask me. I am overwhelmed." "Overwhelmed with what, Dan?" "With conflicting emotions, Jerry. They are chasing each other like clouds over the moon on a clear, windy night." "Dan, you are a riddle." "No, Jerry, but I am unfortunate." "Why unfortunate, Dan?" "Because, Jerry, I was born with too sensitive a nature; as fine cloth with a soft nap attracts the particles flying in the air, so does my delicate nature invite attack." "Oh, yes, Dan, I see now; you were born with a thin skin." "That's it, Jerry." "Cheer up, Dan, cheer up, my boy; you are better off than the other fellows born with the bark on; they cannot feel the play of the emotions, and are impervious to both joy and sorrow. Cheer up, Dan, my boy; it's all in a lifetime. Remember the lines of Gerald Griffin:

"'Joy has its measure,
We live but to die.'

"Jerry, the sky is clearing, I feel myself bracing up; your cheering words, Jerry, have inspired me with new hope and infused into me a new energy; I feel now refreshed and able again to renew the fight against gloomy thoughts. I have now completely mastered my emotions." "Dan, the emotions are like a spirited but unruly steed, best controlled by whip and spur. Coaxing won't do, Dan; it is adding fuel to flame—the whip and spur, Dan, the whip and spur, and ride him into submission. As the saying goes, 'You must fight the devil with fire.' Dan, you have heard, 'Like cures like,' or, as old Dr. Gee used to say, '*Similia similibus curantur.*' Indeed, he said it so often that all the babies on the block have it pat and know it by heart." "Jerry, please don't mention that old homœopathic fake; his name sends a chill through me. I have no use for him. If his skin was mounted, I have no doubt that the directors of the Museum of Natural History would find a corner for it. Yes, Jerry, my emotions almost choked me, but I finally choked them; yes, Jerry, I gave them the whip and spur, the whip and spur, Jerry. You asked me, Jerry, why I grew sad. It was at the mention of the name Evangeline. That was my mother's name, a name and memory dear to me. I had a sister also of that name, who retired into a convent early and died young. Jerry, it was these sweet and sad memories that overwhelmed me, but you are a tower of strength to me now, and I feel comforted in the shadow of your presence, buffeted about, as I was, by the winds of fortune, and sailing aimlessly on the sea of destiny. It was a kind fate that listed me to this port and a providential hand that gathered me under the wings and made me the medical guardian of the physical welfare of our noble circle, the worthy knights of the Order of the Golden Rod, of which you, kind friend and brother, have the honor to be presiding officer. Don't you know, Jerry, you should be a happy man?" "Why so, Dan?" "Because you are in the midst of such kindness, tenderness, and loveliness, surrounded by an affectionate and confiding family, and drinking deep draughts of domestic joy—a joy I don't begrudge you, but one too great for me to hope for. Jerry, might I dare to hope?" "Yes, my boy, hope and wait. They say all things come to him who hopes and waits, Dan." "Notwithstanding this proverb, Jerry, I might hope and wait until the crack of doom before a thing—did I say a thing?—no, I meant an angel like Evangeline would come in my way." "Why, Dan, I declare you are in love." "I am, Jerry."

Dr. Quick tapped his bell for an attendant to fill up the mugs again, when suddenly Mr. Sparks was called to a distant table to settle a quarrel between worthy brothers of the Golden Rod over a card game. Dr. Quick, being in a hilarious mood, grew affectionate toward the waitress, a winsome barmaid, of whom the café of the Golden Rod was proud. She resented his familiarity with spirit, and it was only by the coolness and tact of the sergeant-at-arms and the master of ceremonies that a row was averted, as the vice-president, a noble knight of the Harvest Moon Lodge, was head and ears in love with the buxom lass.

The president, Mr. Sparks, a man with great common sense, took in the situation at a glance, and, with the aid of a trustee and two censors of the lodge, hustled Dr. Quick into a cab, where he persisted, in spite of the jeers of the driver and the protests of his brother knights, in singing "Sweet Evangeline" until he reached the door of his lodgings.

Chapter VII. An After-Supper Chat between Husband and Wife.—"I have bulked it, I have bulked it, Sarah!" exclaimed Mr. Sparks to his wife, as they sat for their usual after-supper chat in their cozy sitting-room over a busy laundry, owned and operated by Trustee O'Rourke, of the worthy knights. "What do you mean, Jeremiah, by 'bulked it'?" said Mrs. Sparks. "Well, Sarah, it is this. You see, times are hard and money is tight; to me just now silver dollars are as big as cart wheels and as scarce as hen's teeth. So you see, Sarah, I have to take in sail." "Jeremiah, you have been sailing already under close canvas; if you take in any more sail, your bark will look like a plucked buzzard, and you will be scudding under bare poles. Now, Jeremiah, come to the point. What do you mean by 'bulked it'?" "Oh, nothing, Sarah, but that I lumped it with Dr. Quick." "Jeremiah, I feel that you have been carousing with Dr. Quick again. I hate that man, because he made it a point to run down Dr. Gee every time he came to see you last winter and spring. On one occasion he told me you had typhoid fever, but Dr. Gee said it was only an attack of diarrhœa. You recollect the morning I had the hemorrhage from the nose, when, after he ministered to my wants, I sent him in to see you, much against his will and yours. He told me on that occasion, a thing I knew beforehand, that you treated him with scant courtesy, refusing to give him a history of the case; but enough was learned, nevertheless, to enable him to make a positive diagnosis. You also recollect, Jeremiah, just this time a year ago, when according to Dr. Quick you had your first attack

of tuberculous meningitis. Dr. Gee laughed heartily when I told him of your symptoms, and said you had only hemicrania, that tuberculous meningitis was a fatal disease, that if the diagnosis was correct treatment was useless. To my pleasure and surprise, Jeremiah, you and I danced at the hop of the Golden Rod after Dr. Quick made the fatal diagnosis. After that incident I had no faith in your lodge doctor, but was drawn closer to Dr. Gee, who I felt was a thorough physician, besides being a true friend of the Sparks family. Dr. Quick knew then I did not regard him with a kindly feeling, as I took no pains to conceal that fact; it seems to me, a mutual dislike sprung up between us." "Now, Sarah, I want to tell you something. Kindly listen to me. This is how it is. I can be sick when I feel like it; I have only to touch a button—Dr. Quick does the rest. I just say 'Hello!' to my lodge doctor; he comes at my call like Rover (Rover jumped from the hearth at the sound of his name from his master's lips); and, Sarah, I only pay him $1 a year. Just think, Sarah, $1 a year! What a cinch, Sarah! So much talent, and so cheap! You see, Sarah, there are about one hundred of us noble knights, just a hundred; we will not take another member. That means $100 for Dr. Quick. Of course, deducting his carfare, it means a little less; but, Sarah, as his legs are very long and his understanding is great, he really does not spend much carfare. He has a knack, Sarah, of standing in with us boys, being one of ourselves; of course we leave no stone unturned to put him through, by throwing every nickel possible in his way. Yes, Sarah, we do what we can for the poor young fellow, as he is very obliging to the knights and handy around the lodge; he is a knight himself, too, Sarah, otherwise he could not be our doctor. Our druggist also, Sarah, is a knight, and we get our prescriptions compounded for little or nothing, because our knightly brother gives us the benefit of a copartnership. Sarah, the framers of our constitution were great and good men; they anticipated our every want and supplied our every need. They inserted a sick-benefit clause to provide for our families, and there is a burial fund too, as I told you on a previous occasion. Thoughtful knights these—legislators great and good. Their motto is ours, 'One for all and all for one.'

"By the way, Sarah, I have a bill for $50 from that fossilized antiquarian, Dr. Gee, for six months' professional services rendered to you and Evangeline." "I think it is a very reasonable bill, Jeremiah. I thought it would be twice that." "It was, Sarah. He took fifty per cent. off." "Well, that is very reasonable, Jeremiah, and exceedingly generous on the part of Dr. Gee—noble old gentleman that he is. Only about $1.50 a visit, including two night calls." "Sarah, how can you call that reasonable? You remember, I counted the calls Dr. Quick made on me last year—two hundred and seventy at this house, and I made two hundred calls at his office—and for all this, just think, Sarah, I paid Dr. Quick but $1. How does that compare with your Dr. Gee? Put that in your pipe and smoke it, Sarah, and you and Evangeline compare notes and see who is cheaper—Dr. Gee or Dr. Quick; and further, allow me to tell you, Sarah, I don't have to wait twenty-four hours for my doctor as you have sometimes for yours, as often he is busy with other patients, sometimes he has rheumatism, and other times he is under the weather; with Dr. Quick things are different—he is as sound as a young colt and quick as his name implies, and, as I told you a minute ago, he comes at the tap of my bell. Sarah, you recollect my pneumonia last winter, my gastritis in the spring, my appendicitis in the summer, and this fall my terrible attack of tuberculous meningitis, not counting the frightful attack of typhoid last Christmas. Sarah, it's awful, what I went through; my constitution must be as tough as hickory wood, to stand the strain of so much sickness. I must have my horoscope cast, Sarah, as I think I was born under a lucky star; if I were not, the daisies would now be growing over me, and I would probably be forgotten by all—not all, Sarah; I am sure you and Evangeline would make pilgrimages to my tomb and scatter wild flowers there to mingle with the daisies." "Jeremiah, darling, stop—I shudder! It will be only too soon if ever I should be forced to contemplate a disaster so overwhelming to myself and Evangeline as that would be." "Yes, Sarah, I am fortunate in my numerous sicknesses. You know how the Rev. Mr. Black died from pneumonia in four days' illness, and how he was cremated, to the horror of his congregation, to whom he preached in humility and hope for thirty years, and always emphasized the resurrection of the body, never forgetting the tomb and the grave clothes, how, to their pain and surprise, his last words were emphatic and explicit, that his body be cremated and his ashes scattered to the four winds of heaven. It was only last night, Sarah, that I was told confidentially that Dr. Black's life was a sacrifice offered up by a bungling physician on the altar of his stupidity, who at the last moment consented to see Dr. Quick in consultation, though asked and requested by the family to take in a consultant at the outset. Yes, Sarah, Dr. Gee has many sins to answer for; they are piling up every day. His judgment and his reckoning must be terrible; I shudder to contemplate that unfortunate man's future. Yes, Sarah, I heard that the Rev. Dr. Black could have been saved but for the stupidity of your old physician, Dr. Gee. My informant said there was nothing to him but a name, only a name, Sarah. Doubtless you have heard the old saying, Sarah, 'Get the name of being an early riser, and you can sleep until dinner time.' The name, Sarah, only the name." "I think I can guess your informant, Jeremiah. Was he not Dr. Quick? I heard him whispering to you in the parlor about Dr. Black's death. Evangeline overheard him abusing Dr. Gee." "Sarah, I won't enlighten you on this matter now. I will only say I told Mrs. Black, the clergyman's wife, to get Dr. Quick at the early stage of the disease; I told her he was a brilliant and accomplished physician, and very reasonable in charges. Had she taken my advice, Sarah, her husband, that good clergyman, would be alive and well to-day and in his pulpit, preaching the glad tidings of salvation to his people." "Jeremiah, talk is cheap; others have not such a big opinion of your lodge doctor as you have." "What do you mean, Sarah? Whom have you reference to? Who are the others? I presume that old razorback, Dr. Gee, has been telling you something detrimental to Dr. Quick's character. If Dr. Quick heard of this he would pulverize that queer specimen of the genus homo for his insolence, as he is very quick—acts on the spur of the moment and thinks later. Sarah, don't you know Dr. Quick came from good stock. On his mother's side he is related to the Websters of Massachusetts, and on his father's side to the Boones of Kentucky. Yes, Sarah, he brought his fiery temper from Kentucky, and his profound learning is an inheritance from his immediate progenitor, Noah Webster, of world-wide fame." "Jeremiah, I believe Dr. Quick has been fooling you about his distinguished relatives, as he has about your numerous diseases. I have heard he is of very humble origin." "Who told you, Sarah?" "Dr. Lee, whom Dr. Butts left in his practice last summer while on his vacation, told my sister, Mrs. Low, in my presence, that as a rule lodge doctors did not amount to much; he said they went into the lodge for what they could get out of it; that they simply used it as a means of locomotion to push themselves along—in fact, Jeremiah, to make stepping-stones of their brother knights, in order to

reach a place of security and emolument for themselves. Dr. Lee said no self-respecting physician would touch the average lodge with a forty-foot pole; there was a fishy odor about it, he said, that savored of the costermonger, mingled with the dance hall. These lodge doctors, he said, delighted to boast of the number of their daily calls, the dangerous nature of the diseases they treated, and the miraculous cures they made. With these fellows, a common cold was the first stage of pneumonia, and a pain in the belly a symptom pointing very strongly to peritonitis. This was a trick they played to catch the unwary, and was inspired by ignorance, ambition, and cupidity. Of the knights themselves, the doctor remarked, they were mostly lubbers of the bread-and-butter brigade, who delighted to strut and masquerade in the armorial trappings and regalia of Richard Cœur de Lion and Henry of Navarre, heroes of a chivalrous age. He said the only fight the paper knights of the noble order of the Golden Rod could make was to overpower the quartermaster and storm the commissary."

Mr. Sparks was visibly affected by Dr. Lee's arraignment of Dr. Quick and the noble order over which he had the honor to be presiding officer. The storm was rising and his blood began to boil, when his good wife kissed him on the cheek and said: "Jeremiah, dear, you know I only repeated what Dr. Lee said." Mr. Sparks, choking his anger, asked casually: "Who is this Lee? Where does he live? Has he an office? If so, when is he likely to be found in?" Mrs. Sparks referred her husband to her sister, Mrs. Low, wife of the armor bearer of the Harvest Moon Lodge, who might furnish the desired information.

Where the Chat becomes Interesting, Showing the Weakness and Vanity of the One and Subtility of the Other.—"Sarah, I had a friendly chat with Dr. Quick last evening, after the lodge meeting in the ballroom over the main hall. He has agreed to attend our family for $5 a year," said Mr. Sparks. "That is what I meant by 'lumping it,' Sarah. It means that I made a contract with Dr. Quick to attend you and Evangeline—myself, of course, included in the lodge contract—for the sum of $5 yearly. Now you know what I meant by 'bulking it,' but of course you know there must be pickings thrown in. We must introduce him around, get him acquainted, and push him along. The only thing he has against him is his youth, as he is not yet quite forty, and, Sarah, you know it's no crime to be young." "Not at all, Jeremiah. I would like to be young again myself, but you know we can't be young always." "You are young yet, Sarah." "Jeremiah, dear, you flatter me." "I mean it, Sarah." "Really?" "Most certainly." "Evangeline, don't take me up that neuralgia medicine from the dining-room to-night—my headache is gone," said Mrs. Sparks to her daughter, in a tone of pleasure and with a satisfied air. Mr. Sparks saw an opportunity in the good humor of Mrs. Sparks to renew the battle for Dr. Quick, whom he knew Mrs. Sparks despised. "Sarah, shall I tell you something?" "Yes, Jeremiah, tell." "Don't you know Dr. Quick has a very high opinion of you—a very high opinion, I assure you?" "A high opinion of me, Jeremiah? Why, I declare I did not think Dr. Quick knew enough of me to form an opinion other than an unfavorable one," said Mrs. Sparks. "Sarah, Dr. Quick is bright, the genius of his family, the Websters and the Boones—a magnificent combination. Courage and ability are stamped on him with the letters patent of nature. He is brilliant, Sarah, and reaches conclusions rapidly, and they are as correct as the sun dial in our garden, and as certain as that Deacon Parr goes to sleep when our good minister, Mr. Snow, is just in the middle of his sermon. I tell you, Sarah, Dr. Quick is a reader of character; he certainly has read and interpreted yours, and in a most favorable light to you, my dear. He said you ought to be decorated with the order of the Red Cross Society for the excellent care you took of me when I had that last attack of cerebro-spinal meningitis four weeks ago." "Jeremiah, dear, you say Dr. Quick interprets me. If so, how can it be otherwise than to my detriment, for I cut him dead at the picnic of the lodge last summer in McNooney's woods when he asked me to lead the dance with him in the cotillion. I gave him a cold stare and immediately afterward danced with Dr. Felix McFadden, sergeant-at-arms of our sister lodge of the Magic Circle. Jeremiah, you fill me with astonishment by imparting the information that Dr. Quick has a high opinion of me." "He has, Sarah." "Jeremiah, dear, what more did he say about me?" "Dearest, if I were to tell you all the good things Dr. Quick said of you, they would fill a book." "Go on, Jeremiah, and tell me all." "I will to-morrow, Sarah. I am tired and the hour is late." "Go on, Jeremiah, go on and tell me all. You can sleep late to-morrow morning. I am willing to go to church alone." "Sarah, I prefer you would excuse me to-night." "Jeremiah, dearest, you know I am kind of sorry I cut the poor fellow so in dancing with Felix McFadden of the Magic Circle, and that cold stare—O Jeremiah, that cold stare!" "Sarah, I see you are a woman." "Why, Jeremiah?" "Because you are inquisitive." "Jeremiah, you know that it is a woman's privilege to be inquisitive." "It is, Sarah: and a man's to be the repository of secrets." "O Jeremiah, has Dr. Quick told you something you will not tell me?" "Sarah, if I tell you all, it will make you too proud." "Jeremiah, dearest, don't you wish to make me happy?" "I do, Sarah." "Then tell me all. Go on, Jeremiah, go on." "Well, Sarah, since I must, I must. You know Dr. Quick calls me by my first name, Jeremiah or Jerry, and I call him Dan: we are bound by an oath of brotherly love. Further I cannot go, as it would be revealing the secrets of a sacred brotherhood. He said: 'You are a happy man, Jerry.' I answered: 'True, Dan, I am. How do you know, Dan?' 'Because I saw your happiness reflected in your good wife's face as you both walked up the aisle of the church yesterday, while I was on my knees at prayer in St. Rutherford's. Jerry, your manly bearing, like a knight of old, erect and stately, commanded the attention of all; but, let me add, admiration and respect were centred in your good wife, who walked by your side, and whose queenly presence overtopped and eclipsed that of any woman there. Indeed, her youthfulness and beauty almost rivalled that of her daughter, Evangeline, who later knelt at her side in prayer.'" "Jeremiah, he talked of Evangeline too, did he?" "He did, Sarah." "Why, I thought he was very sweet on Miss Tubbs, Vice-President Tubbs' niece." "Oh, that was only a passing fancy, dearest." "Then he did talk of Evangeline, Jeremiah?" "You ought to have heard him the other night, Sarah." "Was he as full as when at Mulcahy's wake, Jeremiah?" "Yes, he was full and happy, Sarah." "My dearest, you say he talked of me and Evangeline?" "He talked of Evangeline continually, Sarah." "Jeremiah, I am awfully sorry now I cut him so at McNooney's woods. My darling, when is the next picnic?" "No picnic, this fall," said Mr. Sparks, with regret in his manner, "as the season is far spent: but when the moon is full we will have a husking-party at Gilhooley's, the chamberlain of the Forest Rangers." "Jeremiah, give me the almanac. Oh, it's so long, it's so long. The moon should be full four times a month." "Sarah, you want to accomplish the impossible and subvert the order of nature." "Jeremiah, I want to accomplish my purpose. I do now really feel ashamed." "Ashamed of what?" said Mr. Sparks. "Of how I treated that dear, good man, poor, kind Dr. Quick. I

hope he has forgiven me." "He has, Sarah; he said so last night." "Jeremiah, I knew I was good, because you so often said so, but it was left for Dr. Quick to discover it in a new light and impress that discovery on you, as I hope he has on all. Oh, my, my! I can hardly forgive myself for dancing with McFadden of the Magic Circle, and the cold stare I gave the poor, good, thoughtful Dr. Quick! Jeremiah, dearest, you were right, as you always are. I do now myself think Dr. Gee rather superannuated. However, he is going to move up town the 1st of May; it will furnish us with a respectable pretext for dropping him. If he makes any inquiry afterward, we can say we are never sick—that the neighborhood has got very healthy since he moved away. Jeremiah, darling, I have a favor to ask of you. Will you grant it?" "If I can." "You can, Jeremiah." "All right, then, I will. What is it?" "It is this. I want you to take a chill and shake as hard as you can, just as you used to do before when you wanted to be put on the sick list, for a rest and a week's benefit, and went fishing on the quiet." "Sarah, you are giving me away." "Jeremiah, it is only between ourselves. You know we are the guardians of each other's confidences. Get into bed now. I will cover you up with blankets, put hot bottles to your feet, and rub your face with my vermilion powder; it will make you look feverish. We will tell Dr. Quick you had a spasm, then a chill, after which followed a high fever and a profuse sweat. Get into bed quickly, dearest, until I make my arrangements and put the room in order. Everything is ready. I will now run to Mr. Brown's, the lodge druggist, down the street, and ring up Dr. Quick." "Sarah, you know Mr. Brown is in bed, as it is quite late." "Jeremiah, I will find a means of awaking him. You know it is only half-past twelve. I want the telephone. I will run quickly. I anticipate no mishap—the moon is half full and shining brightly. I will call my mother into the room to comfort you while I am gone; but, dearest, don't attack her again on that mortgage transfer question, as she might have another of those fainting-spells. Good-by, darling, for a few minutes."

"Sarah, you were not long." "Oh, Jeremiah, I had a dreadful time to wake up Mr. Brown. He could easily take rank with the seven sleepers. I heard him snoring outside the door; I had to ring, ring, ring!" "Sarah, come here. I have not kissed you since our silver wedding last week, but twice." "Let me go, Jeremiah, let me go. You are too profuse. Let me go—I see Dr. Quick running up the road; he has entered the lawn. Evangeline, bring me my curling-tongs, quick! quick! Evangeline, the curling-tongs, the curling-tongs, and the Jockey Club—it has the most delicate odor. The peach-blossom powder, the peach-blossom powder, mother. I see him coming, I see him coming. He is at the door. Quick! quick! Evangeline, or you are late!"

Chapter VIII. When Occurs the Accidental Meeting of Friends. Its Influence on the Practice of Medicine.—Immediately as Dr. Gee was about to finish his story, all with one voice exclaimed, "Come in," in response to a knock at the cabin door. It was the steward come on board; he remarked that he was rather late, being detained half an hour in watching the antics of a curious old man who was sitting on the stringpiece of the quay in the immediate vicinity of their sloop. "What does he look like?" said the captain, "and why did he attract your attention?" "Because he was talking to himself and opening and closing a satchel at intervals," said the steward. "He took from the satchel a shining steel; it looked in my excitement like a pistol, and I was afraid he would shoot me before I reached cover behind an old anchor on the dock. As I peered from my place of safety, I saw it was a long and peculiar instrument, having a handle and blade not unlike a small oar." "You said he was talking to himself; what did he say?" asked Captain Post of the steward. "He said, 'He has robbed me of my patients, vilified my character, and set me adrift on a cold and uncharitable world, that he might drive me to the poorhouse or the insane asylum.'" Dr. Gee, becoming interested, remarked: "You say he is an old man, steward. Won't you describe him more minutely?" "Well, he is tall and thin, with shaggy eyebrows and a keen, searching eye, in bearing erect and dignified, with flowing beard frosted by the winters of many years: wearing a long military coat, Kossuth hat, and buckle shoes." "It is Dr. Butts," said Dr. Gee; "the instrument he was handling was a forceps. How did you come to observe him so minutely, the night being so dark?" "It was in the glare of the electric light up there. Look through the window; it is as bright as noonday," said the steward. Dr. Gee continued: "He was doubtless practising on imaginary patients, having none other since the advent of the lodge doctor. He has one of his moods on; he gets them occasionally with the blues." "Who is the subject of his soliloquy?" asked the hostess, Miss Post. "Oh, that scoundrel, Dr. Quick, of lodge notoriety, of course," said Dr. Gee. "Dr. Butts is an equal sufferer with myself from the tricks and machinations of this man." "Invite the stranger aboard," said the captain; "he may refresh your memory on facts that doubtless have escaped your mind and cast further light on Dr. Quick's motives in bankrupting brother physicians, gentlemen of his cloth."

Dr. Gee whispered to Captain Post, as they descended the gangplank in quest of Dr. Butts, not on any consideration to mention the fact of his attempt at suicide. "Rest easy on that matter, my friend; your secret is safe in the keeping of my daughter and myself. We have been the repository of secrets before. Yes, I repeat, rest easy; we will extend the same courtesy to you as to others who have gone before you."

"Dr. Gee, you must be fatigued from the recital of this story; it being personal and so vitally affecting yourself, can only increase that fatigue." "I am fatigued, and feel hardly able to do justice to the concluding chapter in the history of this iniquitous scoundrel," said Dr. Gee to Miss Post. He continued: "Since Dr. Butts has suffered equally with myself, he is acquainted with all the facts in the case and can take up the burden where I laid it down, thus bringing the sad story to a conclusion. It is now eleven o'clock; the moon will be up at midnight, to light Dr. Butts and me to our humble lodgings." "The moon has little significance in the vicinity of great cities," said the captain. "The street lamps rob her of her glory. In the tropics and near the equator, where night falls suddenly, the moon is a special favorite. The sloops in the harbors and the ships in the bays look anxiously for this moon, and there on people's lips are the lines:

> "'Waiting for the rising of the moon,
> And for the evening gale.'"

"It was a piece of good fortune that sent you this way to-night, Dr. Butts. You will entertain and instruct us by sharing the labors of a friend; the interpolation will add zest to the story, while making its truth more apparent and impressive," said the captain. "A task has been imposed on me to-night," said Dr. Butts, "which I am afraid I am not equal to, especially in coming after a master so skilled in the art of weaving facts into story, and telling that story in a manner unique and impressive and with a gracious good will that adds to its power and virility. Since, however, it is the pleasure of the company that it should be brought to a conclusion by me, I will endeavor to be fair to the parties concerned, while point-

ing out the manner in which the lodge doctor affects the practice of a profession so dear to my colleague and me. I repeat, a task has been imposed on me to-night, but it is a pleasant one; it relieves one's feelings to ventilate them on an old and arch enemy, and Dr. Quick has demonstrated by the recital of his methods that he is such. This lodge doctor has from the beginning of his career been opposed to honest practices, and from this fact is hostile to the interests of every painstaking, conscientious physician. He is secretly at outs with the whole army of practitioners, not so much for personal or individual reasons or dislikes, as because they interfere with his schemes and designs to climb to the top in his profession by ways that are dark and by tricks that are transparent. We have seen him leave the highway to cross lots where no trespassing is permitted and creep stealthily through the back door, that he might be accounted in the ranks of the worthy. He dared not face the censor, for fear of being rejected as unworthy and turned back. He was well aware, when he entered into a humiliating and disgraceful contract with a confederacy of men designating themselves a lodge, to be their body servant and pound keeper, or, as they called it, their medical director for the paltry sum of $1 a year from each member, that he was dishonoring the profession of which he claimed to be a part. These hundred men, banding themselves together and constituting a court, imposed conditions on him which still further degraded him and reflected on his profession; it was stipulated that he must qualify to be one of them before he could be eligible to this office they had up at auction—in short, he must be a knight of their order; and further, he must be the lowest bidder. Their contract with this lodge doctor is ironclad and on a strictly legal basis, the wording unmistakable and explicit. This physician, really only a vassal and body servant, has to do the bidding of his masters; as a rule, he tries to please by always obeying his lodge brothers. To the familiar greeting, 'How do you do, doc, old boy?' from his knightly brother, he responds, 'I feel bully, Jimmie; how do you think you feel yourself?' To this good-natured banter may be added a smile or a glass, as circumstances may permit, but his lodge brother reserves to himself the right to be critical, severe, and aggressive, and often the vassal doctor dares not approach his master until his wrath is spent and the clouds of his displeasure have rolled away. His hauteur being dissipated, he may condescend an interview or appoint a time for one, or perhaps might be disposed to be convivial. This lodge doctor, by his contract with his lodge, must be ever ready to run to the bedside of a brother member, night or day, late or early; that member has the precedence and right of way over all others for his vassal's services; he, the brother, has letters patent to that effect locked up in the safe at the rooms of his lodge, or perhaps has the resolution framed and hung up in his bedroom, that it may be read by his physician, better to remind him of his duty; at least, it is certain the original resolution is reposing in an iron box, and the keys of that box in the hands of the armor bearer and keeper of the scroll; those letters of marque, the magna charta of his manhood, are guarded well, resting in iron coffers, and hang like the sword of Damocles over the poor vassal's head. If he is tardy, or if he talks back to the insolent demands of his erstwhile brother because he did not run quicker or because he waited to dress before obeying his master's summons, he is sure to be disciplined, fined, or deposed at the next meeting of the lodge. This poor wretch has attended the famous hundred for the fiscal year just passed for the munificent sum of $1 a head. During this year he made six hundred calls on his family of brothers, and they returned his visits by making about nine hundred at his office; this would make them more appreciative than he, for they go him one better; they visit their servant's office on the slightest pretext, and often they persuade the poor man that they are sick, for reasons well understood by both and told by Dr. Lee to Mrs. Bly in the presence of Mrs. Low and her sister, Mrs. Sparks, wife of President Sparks of the noble order of the Knights of the Golden Rod. On examination, we find twelve hundred calls on Dr. Quick's ledger for the calendar year just closed as medical director of the Knights of the Golden Rod. According to Dr. Lee, a careful observer, Dr. Fly, of the Harvest Moon Lodge, made sixteen hundred calls on his constituency of brothers, numbering one hundred and ten souls, for which he received $105 for his year of service just ended now and for good, as he was not re-elected beca .se of inefficiency. Some of the members brought charges that he made only two calls a day on a brother suffering from grippe, when the bylaws demanded three or even four; they said this disease needed constant watching, lest it should develop into pneumonia. It appears that Dr. Fly received seventy cents a head, or one and one-half cents a week, as medical director for his yearly guardianship of the one hundred and ten knights of the Harvest Moon Lodge. Dr. Lee further told me that Dr. Fox came near being defeated at the polls for re-election by the Magic Circle, an exclusive and aristocratic lodge of ancient knights; he received sixty-five cents a year, or about one and one-quarter cents a week, from each individual comprising the lodge, the membership being two hundred. Dr. Brass, a knight himself, underbid Dr. Fox at the auction before the election, and undertook to treat the members for sixty cents apiece as yearly dues; but, as Dr. Fox had powerful and diplomatic friends in the lodge, he triumphed over his almost successful rival. It was further enjoined on Dr. Fox that during his official year, if he was unfortunate enough to break down, as he did the previous year from overwork, he should not have as his assistant Dr. Steel, who had the temerity to talk back to the armor bearer when chided about some lodge matter, but that Dr. Brass should take his place during his inability; further, serious consequences ensued to the members of the Harvest Moon Lodge when Dr. Fly was in Europe, from the inefficiency and incompetency of the aforesaid Dr. Steel, who shamefully neglected his duty and violated a most important amendment to the constitution when he failed to give the sign of the order at a chowder party of the knightly Sons of Rest. It might here be added that Dr. Quick himself had a narrow escape at his re-election, for unsatisfactory treatment given to a brother who contracted a severe cold while attending a picnic in McNooney's woods. It can, my friends, be seen that these lodge doctors receive but the veriest pittance for services which in a perfunctory routine manner must be laborious; they do not average seven cents a visit as compensation from their knightly brothers. These brothers copy very closely the methods of State-prison contractors, who give about one-tenth the value of services rendered. The time of those physicians is almost wholly occupied with their lodges, yet the income each receives from his lodge is less than the earnings of a third-rate office boy. Where, then, does the lodge doctor get his living from? It is on record that he eats well and, thanks to the instalment system, dresses fairly well too. He cannot do this on his office-boy salary; he will collide with the police if he has recourse to the commoner methods adopted by those who don't know how or are too lazy to work; the fellow is too proud to beg. What, then, must he do? A flood of light is cast on his methods as we see him in the person of Dr. Quick, invading households with the members of which he has only the slightest acquaintance, on the

pretext of making inquiry about a brother member who failed to attend the meeting at the rooms of the Golden Rod. We see him operating with the assistance of female confederates. These confederates he equips with a repertoire of slander, and launches them on the households of those he thinks they can most readily influence.

"At about the time the virus from the tongue of his confederate begins to be active, Dr. Quick, the lodge physician, finds it convenient to be on hand to clinch the falsehoods of his female friend, who is as eloquent in his praise as she is loud in denunciations of Dr. Gee, who has been the physician of the family for years. In the opinion of this female confederate of Dr. Quick, Dr. Gee is losing ground every day, misfortune seems to be his companion in his daily rounds, and death marks his patients as its own. She tells artfully how Dr. Gee lost forty patients last year from blood poisoning, and about forty more from his surgical bungling, and numerous others from neglect and general incapacity; she adds: 'Her friends all say they are through with him; she would advise others to wash their hands of him before it be too late, as was the case with Vice-President Tubbs' sister, of the order of the Golden Rod, who lived at Mt. Carmel, and poor Mrs. Yep, the wife of the sergeant-at-arms of the same knightly circle.' These conspirators, Dr. Quick and his female confederates, usually janitresses, busybodies, and silly women, generally pile up falsehood upon falsehood on the character of Dr. Gee, the family physician, as they have so often upon my own; indeed, they have declared holy war against us and assert that we are dangerous as advisors, treacherous as friends, feeble and inconsequential as enemies. 'Let them retire,' say they, 'to the obscurity from which they never should have emerged — anywhere, any place—to the poorhouse, a sanatorium, or a lazaretto; for the sins they have committed of omission and commission inside and outside the sick-room cannot go unpunished. After all, perhaps the fittest recompense they could make is to rid the world of themselves after making full confession and some reparation for their crimes before their tragic but deserved death.'"

At this hint of suicide Dr. Gee grew deadly pale, a thing that was observed by the captain and his daughter, but not noticed by Dr. Butts, who was absorbed in his story, or the steward, who was absorbed in Miss Post. The story was interrupted for a moment until Dr. Gee, who had fainted, regained his composure, a thing which he did after the windows of the cabin were opened and a volatile salt was applied to his olfactories by the kind hostess. Dr. Gee, being extremely sensitive, was fearful that his effort at self-destruction would become known to his friends, before whom he wished to appear, not as a saint or one holier than thou, but as a man who was able to bear up against adversity and wait patiently for the hour of his justification, which he was sure would come, and when it came make that justification complete by confusing and confounding his enemies and driving them from remorse to confession.

Chapter IX. The Horizon Darkened and the Outlook Not Inviting for the Medical Fraternity.—To-day the shadow of the lodge doctor hangs like a black cloud over the practice of medicine. At first this cloud was no bigger than a man's hand; now it has assumed gigantic proportions and threatens to be precipitated in a social deluge that will sweep away all semblance of the etiquette and traditions that have hung with pertinacity for ages to the toga of the doctor. Three thousand years ago we found him at the bedside of his patient, counting the cardiac impulses, formulating a treatment, and making a prognosis to attentive and appreciative ears. Down through the ages we see dynasties rise and fall, republics come and go, empires laid waste and nations devastated by the sword and pestilence; innovations and experiments appear only to perish on the altar of expediency or be dashed against the rocks of popular disapproval, while old ones again emerge from musty tombs for further test of efficiency and value. Through the mutations of time and fortune the lustre of the doctor was never dimmed, his armor was bright and radiant, shining through the reflected light of a popular approbation and love. Now a change has come over the spirit of this picture; the physician, who was high from time immemorial in popular regard and rested securely in the confidence of the people, is thrown from his pedestal, stripped of his dignity, and pointed at with the finger of scorn by the consorts of this mendacious and insolent usurper, the lodge doctor of the worthy Knights of the Golden Rod. The physician, who was cherished and loved, is to be from this time forward a hewer of wood and a drawer of water to a commonalty which at one time was wont to respect his wish and anticipate his pleasure. The divinity which hedged him in has evaporated, and he stands revealed a creature subject to his environments and the necessities of the hour, fighting in the ranks for his bread and butter like other poor mortals. The tidal wave of slander and mendacity directed against him by the creatures of the lodge has landed him high and dry on the shore of commonplace, to be the companion of the licensed vender and dealer in old bottles; not a semblance of respect left for him now, only that he is handy to have around in time of sickness, just as a chimney sweep is welcome when a flue is stuffed or a plumber when a waterpipe has burst.

"Jupiter, son of the morning, who is the author of our humiliation? Echo answers, 'The lodge doctor,' and we have still lower depths to reach," continued Dr. Butts, "because of our vacillation and pusillanimity and his cunning and cupidity, which will make us the laughing-stock of the world, while it will place him in position more exalted. To increase his influence and dollars, he can be observed after midnight sitting at a table with his crony and bosom friend, the worthy president of the Knights of the Golden Rod, Brother Sparks, talking in a low and earnest tone of voice about his claim to recognition at the hands of the families of the noble knights; he pours slander after slander into the ear of his midnight chum about the character and professional ability of a brother physician. At that table the lodge doctor made dishonorable proposals to his knightly chum, and bid for the family practice as he did for the guardianship of the order of the Golden Rod, by offering his professional services for a song as an entering wedge to the household of his lodge friends.

"Before the advent of this lodge doctor, the family physician had a hearty welcome and an open door through every avenue of society, from the lower to the higher walks of life; his professional fee was established by custom and circumstances incidental to the individual case, cast in the crucible of popular traditions and sealed by the usages of ages. This man, like a disgruntled Malay of the archipelago, runs amuck with professional etiquette, tramples under foot its cherished traditions, and plays hari-kari with its laws and customs; he fraternizes at lodge reunions with every Tom, Dick, and Harry, and for patronage fishes in cheap cafés after midnight with riotous laborers, accounting them as his friends who have labelled themselves as ostensible knights, claiming kindred with chivalrous heroes of legendary renown. This conduct on his part must be fatal to the interests of a profession whose claim to public confidence has heretofore rested on courtesy, intelligence, and self-sacrifice, before the advent of this lodge doctor and now his numerous imitators outside of lodge circles."

When we consider that there are hundreds of Dr.

Quicks attached to lodges in every great city of the Union, and that they are falling over each other in their indecent haste to be first in the race for popular favor, we must recognize that the influence they exercise over the practice of medicine is potent for evil. They are opposed to the existing order of things in the old medical camp, and rebel against its peace and prosperity. It is plain, with those thousands of lodge doctors scattered everywhere, and the lodges themselves at work scooping in everything in sight, from a bank president to a hotel runner, that the days of the old-fashioned family practitioner are numbered and that he will be in time to come as rare as an ethnological specimen of a prehistoric age. This lodge doctor has impregnated the people with the leaven of discontent, and sown the seeds of disrespect for the medical cloth, that must be apparent to the most casual observer of the manners and customs of to-day, compared with those of a generation ago. The cry has gone up long and loud from the medical jackals of the lodge, and it is, "Away with him, away with him! crucify him, crucify him!" Since he has been set adrift on stormy waters, let us—

"Nail to the mast each holy relic,
Set every threadbare sail,
And give him to the god of storms,
To winter and the gale."

51 Charlton Street.

GENERAL EVOLUTION AND NATURAL SELECTION AS EXEMPLIFIED BY MAN.[1]

By LAWRENCE IRWELL, M.A., B.C.L.,
BUFFALO, N. Y.

The evolution of man from a lower form is, of course, a necessary consequence of the general theory of evolution. It was, no doubt, the realization of this fact that caused the attacks upon Darwin and Huxley as soon as "The Origin of Species" reached the reading public.

I must, once more, tell you that the theory of evolution does not entail the descent of man from any existing ape or monkey, and Darwin specifically pointed this out. I am sorry to say, however, that popular opinion still insists that man is a sort of *édition de luxe* of the gorilla or the chimpanzee.

The truth is that man and the anthropoid apes have descended from some common ancestor, and that in the course of time and as a result of natural and sexual selection the branches have diverged, the termination of one branch being man and of others the various tailless, manlike apes. While this common origin does make the tailless apes man's nearest relatives, it does not make them his ancestors. The relationship, however, is about as remote as a fiftieth cousinship, but it is not so far removed as is the relationship between, for example, the chimpanzee and the lemur.

I am anxious to point out that, whatever views you may hold upon religious questions, the admission that man has been derived from apelike ancestors by the process of evolution cannot influence those views, provided you admit—as every sane man must—that the human animal grows up by a process of development from a fertilized ovum in exactly the same manner as every other mammal.

You will remember that I gave the life history of the frog in a previous lecture. I now wish to draw your attention to the life history of man. In this case, as in the case of the frog, there exist the same sequence and the same conditions which the theory of evolution demands. A few coincidences might be explained as mere accidents, but the evidence, taken as a whole, is so overwhelming that one is fully warranted in asserting that each organism in the course of its embryological history repeats in a short period the entire history of the race.

In the embryonic history of man—and of all other mammals—there are peculiarities which, upon the hypothesis of special creation, are not explainable; in the light of evolution they are exactly what one ought to expect.

The ova of all mammals in their earlier phases pass through stages which are capable of exact comparison with those of the frog, of which I gave a detailed account a few weeks since. The ovum divides, forms the germ layers, the nervous system, the notochord, and the muscle plates in the same way. Then comes the same formation of heart and blood-vessels. In man, as in the fish, the heart is at first two chambered; then it becomes three chambered, as in the lower reptiles; and later it developes the four-chambered condition which it retains through life. In the blood-vessels are the same gill arteries as in the frog or shark, running in the same direction and uniting to form the same dorsal aorta. There is the same tendency to form gill slits upon the sides of the neck, and in exactly the same manner, as outgrowths from the throat toward the external skin. Later the blood-vessels change, the gill slits close up, except the first, which persists as the Eustachian tube, connecting the throat with the middle ear.

After a time the distinctly mammalian features become more prominent, and there comes a time when no one can determine between two embryos which is that of a man and which that of a dog. Later the two can be distinguished; but still there is no apparent distinction between the embryo of man and that of one of the anthropoid apes.

Permit me now to draw your attention to a few of the monkey-like characteristics of the human embryo. The great toe, instead of being longer than and parallel to the others, is shorter and extends at right angles to the axis of the foot, just as it does in the foot of the ape. At the seventh month the convolutions of the brain are very close to those of the baboon. According to some authorities, there is at one period a true tail extending considerably below the coccyx of the adult. At the seventh month the entire body, except the palms of the hands and the soles of the feet, is, like that of the apes, covered with hair, the technical name of which is lanugo, and which is usually shed before birth. Even after birth the monkey-like characteristics do not disappear. The young orang-outang clings with its hands to the hair of its mother's breast, and the newly born infant, so weak in other respects, will cling to any surface with sufficient grip to support its weight. Again, if you will watch a full-grown man, who cannot swim, in deep water, you will notice that he moves first one arm and then the other—the very thing he ought not to do—just as the apes move their limbs when climbing a tree.

In structure the differences between man and the anthropoid apes are, of course, very great, but they are differences of degree rather than of kind.

None of the anthropoid apes walks erect with ease, and their arms are longer than are those of man. The apes possess an apposable great toe, which enables them to hold on to almost anything with their feet. Between some of their teeth of both jaws there are spaces, known by the word diastema, and into them the teeth of the opposite jaw fit.

I hesitate to say much concerning man's brain weight, because my views upon this subject were persistently misrepresented two years ago. It is not probable that any normal adult, man or woman, has ever possessed a brain weighing less than thirty ounces; upon the other hand, it is improbable that any anthro-

[1] The substance of the final lecture of a series upon elementary biology, delivered before the Buffalo Society of Natural Sciences, during November and December, 1897.

poid ape has ever been dissected whose brain weight exceeded twenty-five ounces. Please oblige me by refraining from applying any logic to this evidence; my brain may weigh but thirty-three ounces and yours may weigh sixty-four, without your capacity being equal to mine. The extent of the so-called "gray" matter as indicated by the number and complexity of the convolutions is the chief index to the mental capacity of any individual. In considering brain weight, the body weight should always be taken into account.

The process by which man has attained his position in the zoölogical scale has not been due to physical strength, for he has conquered animals possessing far greater strength. His supremacy in the struggle for existence has been due to the superiority of his brain development.

Man possesses many structures of no possible present use, which cannot be explained upon any basis except that of descent from lower forms of life, where they were of value. I have mentioned in a previous lecture the rudimentary muscles for moving the ears; the muscles in the skin which in the lower animals serve to erect the hair, but which in man have no other function than to cause the "goose flesh" of fear or cold. The pineal gland is, I feel convinced, the remnant of a third eye, still distinguishable, though not operative, in the New Zealand reptile, the sphenodon. This gland was formerly regarded by orthodox people as the seat of the soul. The vermiform appendix, which all surgeons, except those present this evening, so dearly love to remove, is a remnant of an herbivorous ancestor which required a large-sized cæcum for the necessary retardation of a too rapid process of digestion. The use of the pituitary body, which is at the base of the nose, is still a mystery.

It is true, of course, that we cannot produce the complete palæontological history of the human animal, as we can the history of the crocodiles, the rhinoceroses, and the horses, partly because palæontology is a comparatively new science, partly because no thorough search has been systematically made—perhaps because the land of man's ancestors is now under the sea. We have, however, such evidence as the Neanderthal man, found in a cave in Prussia, about 1857, and Pithecanthropus Erretus, found in Java about five years ago. The former appears to have been a cave dweller, and his skull differs from that of any known man. The latter ought to satisfy the imagination of those who speculate concerning a "missing link." Some interesting pictures of the skull have appeared in a popular magazine.

One may assert that all the evidence of palæontology, of zoölogy, of comparative anatomy and embryology is unimportant, because the true distinction between mankind and the other animals is to be found in the region of mind and morals.

Now as to the absence of language among the lower forms of life. Of course Darwin saw this difficulty. What is language, I ask? It is the communication of thought, feeling, ideas generally, to others by means of articulate sounds. Can we be sure that the lower animals are not possessed of language in this sense? I trow not. Upon the other hand, a very little observation will convince anybody that many animals not only can but do convey to their comrades their feelings and desires. And he, indeed, will be a bold man who is prepared to deny that the numerous sounds emitted by animals play no part in this conveyance. Is there, I ask, a greater gap between the language used by such animals and the few harsh sounds employed by the lowest savages, than between the language of the lowest human beings and the elaborate speech of a highly educated American or European? The sounds emitted by dogs or horses may seem few, but it is well to remember that, instead of trying to learn what these animals know, we use all our energy in trying to teach them what we know. The natural question is, Where does sound end and speech begin? Who is prepared to draw the line? I venture to assert that the differences are a mere matter of degree. In the face of our ignorance upon this subject and the small amount of attention that has been paid to it, it is well to be very circumspect.

That organs anatomically similar, such as the vocal organs of men and apes, should be functionally different, is to my mind most improbable. The action of our vocal apparatus is dependent upon our organ of breathing, and the manipulation of respiration is partially dependent upon the position of the body. The development of our particular mode of speech is probably a correlative of the erect position so characteristic of man.

The development of language is merely one phase of the much larger question of the mental distinctions between man and the rest of the animal world, and I venture to assert that the law of the survival of the fittest is an abundant explanation of mental evolution. Do not allow any dust to be thrown in your eyes. This question does not involve the mental condition of highly civilized human beings; it is merely a question of the mental differences between the highest animals, below man, and the least civilized human beings.

Everybody knows that the lowest animals are not destitute of intelligence. In Darwin's "Descent of Man," which I urge you very strongly to read, are to be found many well-authenticated facts, showing that the same emotions and characteristics, such as curiosity, imitation, memory, attention, and even reason, are observed in some animals besides man. The love of a dog for his owner is proverbial; maternal affection is strikingly developed in many animals. Monkeys are successful as performers in consequence of their powers of attention and imitation. Ants unquestionably possess memory; and if dogs and cats do not dream, my observation must be very much at fault. Darwin has recounted some extraordinary cases of the reasoning of retriever dogs; and my own experience convinces me that the dogma that man is the only reasoner cannot be supported by any scientific evidence.

There is but one way in which all these facts can be interpreted, viz., by concluding that in all the so-called "higher" mental attributes, the true difference between man and the lower animals is, to quote from that prince of observers, Sir John Lubbock, "one of degree and not of kind."

Darwin's explanation of the psychological side of evolution essentially consists of the application of his principle of natural selection. Let me remind you that, prior to his time, psychology was a mere mass of verbosity and metaphysical pedantry; it was not a science at all, and apart from physiology it is not now and never can be a science. Darwin's discussion of instinct in the "Origin of Species," and the light he was able to throw upon obscure cases by the aid of natural selection, formed a suitable commencement to true psychological science. In the "Descent of Man" he deals with the mental characteristics of man and of other animals in a masterly manner. Congenital mental variation favorable to its possessor is very often transmitted to the next generation; and the continued survival of the fittest from a mental point of view must in time cause a gradual development of the mental faculties. All you need to do is to satisfy yourself that the process of natural selection is the truth, and then the solution of the problem is comparatively simple. The origin of language and of all the higher faculties, including reason, is the result of congenital mental variation, the survival of those best suited to the environment, and the transmission of such congen-

ital characteristics as are of benefit to the individual in the struggle for life. "I cannot doubt," writes Darwin, "that language owes its origin to the imitation and modification of various natural sounds, the voices of the animals and man's own instinctive cries, aided by signs and gestures."

In concluding this very brief sketch, I wish to read Darwin's answer to those who are shocked at the idea of having been descended from ape-like ancestors: "The astonishment which I felt on first seeing a party of Fuegians on a wild and broken shore will never be forgotten by me, for the reflection at once rushed into my mind—such were our ancestors. These men were absolutely naked and bedaubed with paint, their long hair was entangled, their mouths frothed with excitement, and their expression was wild, startled, and distrustful. They possessed hardly any arts, and, like wild animals, lived on what they could catch. They had no government and were merciless to every one not of their own small tribe. He who has seen a savage in his native land will not feel much shame if forced to acknowledge that the blood of some more humble creature flows in his veins. For my own part, I would as soon be descended from the heroic little monkey who braved his dreaded enemy in order to save the life of his keeper, or from that old baboon who, descending from the mountains, carried away in triumph his young comrade from a crowd of astonished dogs—as from a savage who delights to torture his enemies, offers up bloody sacrifices, practises infanticide without remorse, treats his wives like slaves, knows no decency, and is haunted by the grossest superstition. Man may be excused for feeling some pride at having risen, though not through his own exertions, to the very summit of the organic scale; and the fact of his having arisen, instead of having been aboriginally placed there, may give him hope of a still higher destiny in the distant future."

76 West Tupper Street.

ANOMALOUS LOBULATIONS OF THE LIVER.

By W. MOSER, M.D.,

BROOKLYN, N. Y.

The liver generally consists of five lobes, viz., 1, right; 2, left; 3, lobus quadratus; 4, lobus Spigelii; 5, lobus caudatus. The three quadratus, Spigelii, and caudatus are simply small subdivisions of the large right lobe. The left lobe is smaller than the right, and is separated from it by the longitudinal fissure. The falciform peritoneal attachment of the liver, known as the longitudinal (suspensory) ligament, practically divides the right and left lobes on the upper surface. The lobus quadratus, as its name implies, is a quadrate (square) lobe, being bounded by two fissures, viz., longitudinal and transverse, and also by the gall bladder (Heath). The lobus Spigelii is the projecting portion on the back part and under surface of the right lobe. It is bounded in front by the transverse fissure, on the right by the fissure for the vena cava, and on the left by the fissure for the ductus venosus (Gray). The lobus caudatus, so called owing to the tailed mass of hepatic tissue, extends from the base of the lobus Spigelii to the under surface of the right lobe. It separates the right extremity of the transverse fissure from the commencement of the fissure for the inferior vena cava (Gray). The right lobe is about six times as large as the left. I can confirm the statement of Gegenbaur that the lobus Spigelii is very varied in shape, and also that the breadth of the lobus quadratus varies. The five fissures on the under surface of the liver serve to divide the organ into five lobes. These fissures are: 1, longitudinal; 2, fissure of the ductus venosus; 3, transverse; 4, fissure for the gall bladder; 5, fissure for the vena cava. The longitudinal fissure extends from the anterior margin to the posterior border of the organ. The so-called umbilical fissure is simply the anterior half of the longitudinal fissure, and is deeper than the posterior part. The groove made by the longitudinal fissure is a deep one. The posterior portion of the longitudinal fissure is shorter than the anterior, and constitutes the fissure of the ductus venosus. The transverse (portal) fissure is only about two inches long, but it is deep, and extends transversely along the under surface of the right lobe. This is the fissure where the portal vein, hepatic artery, duct, and nerves enter. It also transmits lymphatic vessels.

The fissure for the gall bladder (fossa cystidis felleæ) is an oblong fossa on the under surface of the right lobe, running parallel with the longitudinal fissure. "It extends from the anterior free margin of the liver, which is occasionally notched for its reception, to near the right extremity of the transverse fissure" (Gray).

The fissure for the vena cava is a deep short fissure behind the gall bladder. It is separated from the longitudinal fissure by the lobus Spigelii, and from the transverse fissure by the lobus caudatus. The right lobe has two depressions on its under surface, viz., anterior and posterior. The anterior depression corresponds to the contact of the liver with the ascending colon; the posterior depression is at the point where the anterior surface of the right kidney comes in contact with the organ. These depressions are not fissures, and are more analogous to the effects of constant pressure. The depressions sometimes seen on the upper surface of the liver (Liebermeister's furrows) are due to the constant pressure of the ribs, as in tight lacing, etc., causing atrophy of the corresponding areas of hepatic tissue. They could be mistaken for anomalous fissures of the upper surface of the liver. But any one who has seen several specimens of both can usually distinguish them. Anomalous fissures on the upper surface of the liver have not that distribution; that is, they do not correspond to the region of the individual ribs. Furthermore, I have usually found anomalous fissures of the anterior or upper surface of the liver associated with anomalous fissures of the under surface. Now and then an accessory fissure or fissures may be seen, especially on the under surface, but they are not always very deep. In the few cases of anomalous lobulations of the liver under my observation, I have found the fissures in most instances deeper than, for instance, the fissures of the lobulated kidney of adults. The lobulated kidney of adults is simply the remains of fœtal life, the kidney in the fœtus being normally lobulated. In some lower animals the fissures of the kidney are deep, and so symmetrically arranged as to make each lobe appear like a square.

I have noted in the anomalous fissures of the liver, which of course serve to divide the organ into anomalous lobes, intralobar adhesions. They are not coarse adhesions, such as occur between the parietal and costal pleuræ in disease, or an intralobar pulmonary adhesion, the product of inflammation; but they are fine and admit of being broken up so that the fissure becomes deep, and consequently each lobe becomes more prominent—more individualized. These fine intralobar bands are not the product of disease.

In the mammalia the liver is divided, like the human liver, into two principal lobes, and retains pretty much the same shape. The liver of the orang-outang is like that of man (R. Wagner). The dog and cat are much-lobed animals, having from six to eight lobes. Now, aside from anomalous fissures, which may penetrate the organ in the human being and serve to divide it into anomalous lobes, I have encountered in two in-

stances a small accessory lobe. I use the word "accessory" here in the sense that I would speak of an accessory finger, *i.e.*, another lobe is added to the normal five lobes, in the same manner that a fully developed supernumerary digit is added to the usual five digits; it is not merely a subdivision of any of the five. In addition to the usual five lobes we may find on the under surface of the organ a small mass of hepatic tissue, or a lobe, somewhat loosely attached, movable, as if hanging on a pedicle. These small accessory lobes could be mistaken for an accessory liver. They occur on the under surface of the liver, however, while an accessory liver is usually found on the upper surface, attached to the suspensory ligament.

ANGINA PECTORIS AND CARDIAC PALPITATION—THEIR SPEEDY RELIEF.

By BEVERLEY OLIVER KINNEAR, M.D.,
NEW YORK.

Angina pectoris is usually, in fact, I may say invariably, a progressive disease, almost always terminating fatally; and up to the present the profession has discovered no remedy or remedies which will permanently arrest its course. Tonics, such as iron, arsenic, and strychnine, have thus far given the best results in extending the time between the terrible paroxysms of the disease.

It may be associated with certain forms of organic heart trouble or there may be no serious lesion of the heart itself, and yet the attacks will progress for several years, increasing in frequency and severity, and then terminate fatally.

The pain and distress caused by paroxsyms of the disease are simply indescribable; the intense pain and the sense of suffocation and impending death form a combination of distressing symptoms, greatly to be dreaded.

Have the real causes of angina pectoris yet been discovered, and, if so, are there remedies or any system of treatment which will subdue the seizures and arrest and cure the disease?

Trousseau finds a resemblance between this disorder and epilepsy, and it may also be mistaken for asthma, certain hysterical attacks, myalgia, and intercostal neuralgia, and the early stage of acute pleurisy.

The late Dr. Flint, in his "Practice of Medicine," gives such a graphic description of an attack of this complaint, that I insert it in order to analyze the symptoms, and by so doing suggest some of the leading causes of the seizure. He says: "The patient is suddenly attacked with an intense agonizing pain in the precordial region (usually commencing on a level with the xyphoid cartilage), extending through the back and along the left arm. This pain is of a stabbing character, and produces a sensation of impending suffocation—a feeling as if death was near at hand. There may be true laryngeal pain. At the commencement of this pain the countenance becomes deadly pale and is expressive of extreme suffering and anxiety; the surface is covered with a cold perspiration; the pulse falters and may be almost imperceptible; the respiration is short and hurried; the face is livid, and the patient is unable to lie down or even to move, for the least motion aggravates his sufferings. His consciousness is undisturbed, and his spinal as well as cerebral functions are unaffected; but there may be slight wandering as the attack passes off. Not infrequently the rhythm of the heart's action is undisturbed, and the patient does not even experience palpitation. Sometimes the action of the heart is so deranged that syncope or even sudden death occurs. The pulse may be slow and feeble or markedly irregular. Usually after the paroxysm has continued for a few moments, or at longest for an hour, it gradually subsides. The attacks may come on during sleep. At first there are long intervals between them, but after a time they become frequent. Between the attacks the health may be unimpaired."

What, then, are the most prominent and noticeable features of such seizures? It seems to me the most important symptoms are the pain, the cold surface of the body, and the feebleness or irregularity of the pulse, this latter symptom denoting either great weakness of the heart muscle or abnormal central nerve action controlling its function. This weakness and irregularity are especially dangerous because the patient fears to inspire deeply, believing that the pain will thereby be increased; therefore proper oxygenation of the blood during the attack fails to take place. In a person subject to these attacks they may be induced by physical exertion, mental anxiety, indigestion, and other causes; but, whatever the cause, the features of the seizures are always similar. It is of course well understood by the profession that the nervous system is involved in this disorder; but I have never yet seen any writings which attempt to explain the described symptoms as due to disease of the nerve centres, or upon such a hypothesis to set forth a treatment which, by acting upon central nerve cells, would abolish the attacks of pain and respiratory distress, thus changing the progress from a downward to an upward course, ending in complete recovery.

It is now my endeavor to present such a hypothesis and to demonstrate such a plan of treatment. Pain as a factor may be induced by two chief causes within the body: it may be the result of local pressure, as from tumors or inflammatory enlargements, or it may be a manifestation of abnormal or increased function in the sensory centres of the cerebro-spinal system, evidenced by pain at the nerve terminals connected with the affected centre.

In angina pectoris there is no local swelling at the seat of pain; rather there are a lack of circulation in the painful parts and a contracted condition of the arterioles of the whole surface of the body, demonstrated by the cold body with cold perspiration; therefore it would seem that the pain in the majority of these cases is induced by trouble at the centres of the nerves affected.

In what does that trouble consist? My own belief is that it consists in simple hyperæmia of spinal sensory centres, and my reason for this conviction is twofold. First, because the function of a sensory centre is to induce sensation; and this it cannot do unless supplied with its normal amount of blood, for the reason that the blood is the agent which carries to all organs and tissues their proper nutrition in the form of food and oxygen, and without which neither organ nor tissue can normally perform its function. This being true—and it is—then if an organ or tissue receives an excessive supply of blood in active circulation, the nutrition and function of the part will be increased. Therefore, if there is active hyperæmia in a sensory centre, there must result increase of function, which is increased sensation, which is pain. Secondly, because in a very large number of cases of neuralgia—and in one of angina pectoris—I have cured the attacks by applying cold over the sympathetic ganglia and the spinal cord, the cold expelling the excess of circulation from the hyperæmic centre or centres, with a resulting speedy cessation from pain; and in the case of angina pectoris a glow of warmth follows over the whole body, evidencing an expansion of the arterioles in active circulation in the body and extremities, resulting in a dry surface and the restoration of the normal temperature. The pain ceases at the same time. The case of angina pectoris wholly cured was a severe one in regard to pain, the patient being apparently gripped over the

region of the heart with an icy-cold iron hand, the sensation being that of great pain induced by the pressure such a hand would cause when forcibly closed over the parts held within its grasp. A spinal ice bag, worn once a day for an hour and extending from the fourth dorsal to the third lumbar vertebra, entirely relieved the patient, and now after five years he has had no return of the disease.

The cold surface of the body during the seizures denotes hyperæmia of the sympathetic ganglia, therefore constriction of the general circulation; and the treatment must be such that the blood will be expelled from these centres, and immediately this is effected it will be distributed normally throughout the body and withdrawn also from the hyperæmic spinal sensory centres, rapidly abolishing the pain. This treatment will, I believe, act at once, and give relief in the majority of cases of this dreaded disorder. It meets the indications, overcomes the attacks, and, if used wisely for a time, eradicates the central nerve trouble. Any treatment which will universally dilate the arterioles will subdue the attacks of angina; and the success which has attended the use of nitrite of amyl is, I believe, undoubtedly due to its dilating or expanding action upon the capillaries of the whole body, expanding also the contracted coronary vessels of the heart, and thus restoring strength to the organ by supplying the normal circulation to its muscles.

There is another remedy which I believe will be found most valuable in relieving the attacks of angina, and that is oxygen by inhalation. Oxygen when properly diluted with another gas of lighter specific gravity is readily absorbed by the pulmonary capillaries; and after it enters the circulation its first effect is to dilate the coronary arteries, and a normal amount of blood—saturated with oxygen—being thus added to the enfeebled organ the heart muscle is stimulated and strengthened, and its weakened action immediately overcome in the attacks of angina pectoris. The secondary action of the gas, which I have frequently tested, is to dilate every arteriole throughout the body and extremities, thus universally distributing the circulation in normal amount to the whole organism, and thereby warming the body, exciting renewed and active metabolic changes, and withdrawing the excess of the blood from the hyperæmic sympathetic ganglia and cerebro-spinal nerve centres. My belief is that oxygen alone will speedily relieve the attacks of this disorder; but in combination with cold over the spine and heat to the extremities I have no doubt that it will be found to be the speediest method of relief in such attacks. I am also convinced that if this combined treatment without the heat to the extremities be continued daily for some months, and in many instances for a much shorter time, in the majority of cases so afflicted a cure will result.

It must always be borne in mind that only pure oxygen properly diluted and prepared solely for therapeutic purposes is of any value in the treatment of disease.

The most efficient formula now in use is that of the London Oxygen Hospital, and consists of two parts of pure oxygen, one part of nitrous monoxide, and one per cent. of ozone, to keep the mixture fresh when in the cylinder.

Injurious and not beneficial results will follow the use of oxygen gas, unless it be wholly freed from chlorine and other deleterious gases always present in commercial oxygen.

It may be noted from what has been written in this paper that pure and properly diluted oxygen gas when inhaled induces the same effects upon the pulse, respiration, temperature, and nutrition, as those following the application of cold over the spine; but whether by its action through the blood upon the nerve centres or by its local stimulating effect upon every tissue cell within the body, it is hard to say.

I am inclined to the belief that, being speedily carried by the blood to all parts of the organism, its action is local upon all tissue cells, stimulating them, and thereby causing a universal dilatation of the arterioles and an active nutrition throughout the body.

Cardiac palpitation is, in my experience, very easily controlled in the majority of cases by cold over the spine, applied from the fourth cervical to the third lumbar vertebra in anæmic people or in those run down from overwork, anxiety, or the abuse of tea, coffee, tobacco, or alcohol. In cases of palpitation in those who evidence a tendency to blood to the head, or upper body, with cool or cold feet, or lower extremities, it is my practice to apply the spinal ice bag from the fourth dorsal or the third lumbar vertebra, once or twice a day for forty minutes, taking care to move the bowels regularly and fully but not excessively.

Oxygen inhalation will act in these cases speedily and curatively for the same reasons as those given when speaking of angina pectoris. Oxygen by cylinder is easily administered, as you have only to turn a stopcock, compress the nostrils, place the tube in the mouth, and after complete expiration inhale as deeply as possible, hold the inspired gas as long as you comfortably can, and then exhale slowly through the nasal passages. Two inhalations three times a day, taken standing and before meals, with an interval of two minutes between the inhalations, are sufficient for the daily treatment of cases of angina pectoris and cardiac palpitation; but in a seizure of angina the tube should be placed in one of the nostrils, the gas turned on from the cylinder, and the patient allowed to inspire the gas with the respiratory movements, and thus continue until the attack is quite relieved.

107 East Twenty-Third Street.

Progress of Medical Science.

Nosology of Syphilis.—At the meeting of the Academy of Medicine held in Paris on May 17th, M. Dieulafoy discussed the nosology of syphilitic affections of the stomach. His conclusions may be summed up as follows: Syphilitic lesions of the stomach can and do take various forms from hemorrhagic erosion to a gummatous ulceration. Probably the action of the gastric juice is a factor in continuing the ulcerative process set up by the syphilis. The symptoms of a syphilitic ulceration differ in no way from those of simple ulceration, so that the practitioner should always be on his guard and carefully interrogate any patient suffering from gastric ulcer as to the presence or the reverse of a syphilitic history. Treatment should be begun at once, for in this way a patient may often be relieved by measures in whom otherwise it would appear necessary to perform a surgical operation.—*Lancet.*

The Measurement of Smells.—According to an English journal, Eugene Mesnard, a French botanist, is reputed to have discovered a simple and easy method of measuring the intensity of an odor. He takes advantage of the delicate qualitative power of the sense of smell—that is, of its ability to discriminate between odors, although they differ only by a very little. He finds that if some very characteristic odor be mingled with the one to be measured, there is a certain point where they balance and form what he calls a "neutral odor." In this state the addition of a minute quantity of either scent causes that one to predominate, and thus a very "small smell can be detected and measured."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 16, 1898.

THE DECADENCE OF THE LATIN RACE.

THE opinion appears to be universal that the Latin race as a whole is on the down grade. That such is the case with the Spanish branch is a fact too palpable to be denied. Italians, too, are becoming themselves conscious that they are unable successfully to compete with the Anglo-Saxons. Even in France there exists an uneasy feeling to the same effect, and some of their writers have recently been bewailing their position and inquiring into the causes thereof. Indeed, the subject has of late been made the theme of much discussion in France and Italy, and a number of ingenious theories have been put forth in explanation of this—to inhabitants of those lands—disquieting state of affairs. *The Lancet*, commenting on this in a leading article, says: "The subject so started has evoked many interesting contributions to its discussion, but of all yet given to the world the most temperate, the most scientific, and the most conclusive is that of the professor of physiology in the University of Turin, Dr. Angelo Mosso. He takes his text from the brilliant book of Signor Guglielmo Ferrero, 'L'Amore nella Civiltà Latina e Germanica,' and cites one of its most pregnant passages on which to hang his discourse. 'The Englishman and Scandinavian,' says Ferrero, 'are sexually less precocious and cooler blooded than the Frenchman or Spaniard, and in this organic difference lies the root of nearly all the other psychical differences of the two races, northern and southern.' Not accepting this thesis absolutely, Dr. Mosso interprets it with considerable modifications, which seem to us scientifically well founded. 'Life,' he admits, 'develops more intensely, more rapidly in southern latitudes. In India the female becomes a mother at thirteen, in Italy she may become so at fifteen, in the people of the north at eighteen. As nothing happens in one sex which has not a 'harmonic correspondence' in the other, so we may say that the youth of the Latin race are made men two or three years before the youth of the north." But Professor Mosso, while conceding that in the organic differences of the two races is to be found to a certain extent the cause of the inferiority of the Latin to the Anglo-Saxon, yet does not allow that this by any means covers the whole question. He thinks, and probably rightly, that it is in the physical and mental training of the races that the cause of much of the success of the Anglo-Saxon must be sought. Dr. Mosso declares that to the American and English system of education, of instilling into the minds of the young a love of healthy out-of-doors exercise, is largely due the greater physical and mental robustness of the Anglo-Saxons.

So far as the Spanish race is concerned, their deterioration, like that of the Turkish race, must be almost wholly ascribed to the gross ignorance of the masses and to the corruption of the upper and governing classes. Indeed, there would appear to be many points of similarity between the inhabitants of Spain and those of Turkey. The Spaniards undoubtedly possess much of the Mohammedan pride and fatalism, owing perhaps to the infusion of Moorish blood in their veins. *The Spectator*, in a recent issue, gives an interesting estimate of the Spanish temperament. "Two qualities, and only two," says this journal, "certainly differentiate Spaniards from the other southern races of Europe, but they are qualities displayed in such excess that they appear to constitute an entirely separate national character, which in hundreds of years has never changed either in fact or in the impression which it makes upon the remainder of mankind. One of these qualities is a peculiar kind of pride, and the other is a steely callousness. . . . It is a quality of pride which distinguishes the Spaniard alike from the Italian and the Frenchman. A personal dignity quite apart from mere vanity appears to be as essential to him as freedom to the Anglo-Saxon or order to the German. He must, however, be callous as well as proud, or he could not let women and children die of want, or exult in the risk to human life, which, after all apologies have been made, is the true cause of excitement in the bull-fight."

SERUM TREATMENT FOR FOWLS.

ANIMALS have played a prominent part both in the discovery of diseases and of their antitoxins. If it had not been for experiments on animals, it may be said with assurance that bacteriology would not be in the advanced state that it is at the present time. Thus it appears only just that they should participate in the benefits that have been brought about chiefly through their agency. We are therefore pleased to announce that the discovery has recently been made that certain diseases peculiar to fowls have been shown to be amenable to the serum treatment. Dr. Stevenson, of London, Ontario, who is a large fowl rearer, has been making investigations into the disease known as roup, and which is stated to be the cause of death in about eighty per cent. of chickens. This disease also affects many others of the feathered tribe. The results of these investigations has been clearly to prove that roup is of an infectious nature. The normal temperature of a fowl is about 105° F., but when it is suffering from roup the temperature generally runs up to 107° F. In some cases paralysis supervenes. That the disease is communicable by means of drinking-dishes and drinking-troughs was definitely demonstrated by experiments and the bacillus was isolated. From the symptoms of the complaint and from careful examina-

tion of the bacillus, Dr. Stevenson came to the conclusion that roup in chickens was similar to diphtheria in man, and also that it was caused by a specific germ identical with bacillus of Klebs-Loeffler. It was then determined to try the effects of hypodermic injections of diphtheria antitoxin serum. This was accordingly done, and it is declared with the most satisfactory results. If this account be true, and there seems no reason to doubt its genuineness, although Dr. Stevenson can hardly expect that his name will be handed down to posterity linked with those of Behring, Pasteur, or, maybe, Sanarelli, still he deserves his meed of praise as a benefactor, both to the rearer of fowls and the consumer.

COLD TEA AS A BEVERAGE FOR OUR SOLDIERS IN CUBA.

THE perfect portable filter has yet to be invented. Those in use now, although in many respects satisfactory, have drawbacks that to a large extent nullify their efficacy. As has been recently pointed out by Dr. Sajous, a filter, thoroughly to answer the purpose required by a soldier in the field, should be strong, portable, capable of turning out a large quantity of water in a short time, and so constructed that it can be easily taken apart and cleansed. No filter at present in the market fulfils all these conditions. Undoubtedly the most certain way of sterilizing water is by boiling, and it is the best method of combating the diseases incidental to a tropical climate. Nevertheless this mode of sterilization is open to objections, not the least of which is that unless the water so treated is subsequently oxygenated it is a very tasteless fluid. The late Mr. Ernest Hart was a strong advocate of what he termed "the doctrine of the tea kettle," and many distinguished Indian commanders have testified in favor of tea as a means of quenching soldiers' thirst when on a long march in equatorial lands. The men under the leadership of Sir Herbert Kitchener during the recent campaign in the Soudan, were allowed no alcoholic stimulants whatever, but performed their long journey through the desert, ending with the victory at Albara, on cold tea.

The *Scientific American* of July 2d has an article lauding the refreshing qualities of cold tea, in which it says that "one of the most efficacious ways of quenching thirst, when there is a strong pressure for uninterrupted action on the part of the soldier, is to fill his canteen with tea. Of course this would be made from boiled water; and the addition of a few drops of lemon juice would increase its power of exciting the salivary glands to greater activity, and it is an expedient often resorted to when it is desirable that the least possible amount of liquid should be ingested. The use of tea is still further approved by the testimony of experience. Sir John Hall says: 'In the Kaffir war (1882) a march was made by two hundred men in which one thousand miles were covered in seventy-one days, or at the rate of fifteen miles a day, without wines, spirits, or beer.' Officers in India, when marches were made through malarious regions, had an opportunity to test the virtues of tea. Lord Wolseley urges its use, and the experience of the Canada lumbermen confirms its value. They spend the winter in the backwoods in the hardest sort of labor and are exposed to a freezing temperature, and while no spirits are allowed they have an unlimited supply of tea."

The fact has been conclusively proven that, when men are undergoing severe exertion in extremes of temperature, alcohol in any form is not only unnecessary but is absolutely injurious. Tea infused in boiling water is certainly much more palatable than insipid boiled water, as well as being practically harmless. Therefore there would seem to be no reason why our army in Cuba should not follow the example of their British brothers in arms in India and Egypt, and march and fight refreshed and invigorated by cold tea.

NEEDLESS NOISINESS.

SINCE we first began to advocate in the interest of the sick and nervous a diminution of unnecessary noise in the metropolis, little change can be said to have taken place. Still, in spite of the increased number of boys yelling out their "extras," and in spite of a seeming general lack of interest in the whole matter, there are signs of encouragement which we are glad to note. A correspondent writes to point out what may be done by personal effort.

Encouraged by an editorial in the MEDICAL RECORD, in which some such suggestion was made, he states that a house-to-house canvass was made "in the interest of a quiet afternoon," and all owners or occupants of houses on two adjacent blocks were asked to refrain from patronizing or financially encouraging any street musicians, venders, or would-be purchasers after one o'clock each day, and to discriminate in general against the unnecessarily noisy ones. By this means, and with a little pains taken in interviewing noisy fruit and flower sellers and bottle buyers, giving them to understand that they will meet with little success in the neighborhood if they persist in causing annoyance, the particular streets in question are reported to have become much more habitable, especially in the part of the day when invalids need their quieting nap and ladies and babies rest.

One of the most encouraging facts to be noted is the establishment of an anti-noise society in this city. It has not yet been incorporated, but hopes soon to be. A physician, Dr. Gairdner, is at the head of the project, and we wish him all success. Through the society's efforts a law was passed forbidding the hauling of heavy iron through the city's streets, unless it is packed so as not to cause the deafening din so well known to all who have heard it pass over the cobbles. A petition, signed by a number of prominent bankers, has just been presented to the Council of the city praying for the passage of an ordinance forbidding the shouts of fakirs and the "extra" cries of newsboys.

If society effort and individual effort go hand-in-hand, and every physician speaks to the alderman of his district concerning the matter and the people's desires, the day may come when will be added to New York's other attractions that of comparative peace and quiet.

News of the Week.

Dr. Nelson H. Henry, of this city, has been appointed by the President division surgeon of volunteers, with the rank of major.

The British Medical Association.—The names of those selected to deliver the annual orations at the Edinburgh meeting of the British Medical Association during the last week in July have been published. Dr. T. R. Fraser will deliver the address in medicine, Dr. Thomas Annandale that in surgery, and Sir John Batty Tuke that in psychological medicine. All the orators as well as the president, Sir Thomas Grainger Stewart, are residents of Edinburgh.

Dr. Frederick Holme Wiggin has recently been appointed by the commissioner of public charities assistant visiting surgeon to Bellevue Hospital.

A New Line of Goods at the Health Department.—The daily papers announce that the board of health has decided to put on public sale its brand of antistreptococcic serum. The serum has been made for a year past and has been furnished to some of the city hospitals, but has not before been in the market. By way of inducement the board has decided to send out a circular stating that it will make free bacteriological examinations of any cases which have been treated or are to be treated with the serum.

Dr. B. Sachs, of New York, has been elected a foreign member of the Moscow Society of Neurology and Mental Sciences.

A Yellow-Fever Syndicate.—It is reported that Sanarelli, the discoverer of the alleged bacillus of yellow fever and originator of an antitoxin serum for the cure of the disease, has sold the rights of manufacture of the latter to a firm in Montevideo for $30,000 and a royalty on all sales.

Medical College Consolidation.—The era of mushroom medical schools seems to be drawing to a close, and that of consolidation of existing schools to have begun. We have noted the union of the University and Bellevue in New York and of two colleges in Atlanta, and now it is announced that the medical department of Niagara University has been consolidated with the medical department of the University of Buffalo. This is a healthy movement, which we hope, in the interests of sound medical education, will not be checked until it has spread over the entire land.

A Medical Duel.—We learn from the *British Medical Journal* that one of the absurd French duels was recently fought between two doctors in Paris. Dr. Jean Charcot, son of the famous physician to the Salpêtrière, considering the memory of his father insulted by an article written by Dr. Lagelouze, in the *Opinion Médicale*, challenged the writer. The duel came off on June 9th, the weapon used being the sword. M. Charcot "received on the upper part of the thenar eminence a buttonhole wound four centimetres long, making it impossible for him to go on." Honor was declared to be satisfied, and all ended happily A formal protocol was drawn up in which the circumstances of this terrific combat were set forth in detail with a solemnity worthy of the occasion.

Infantile Scurvy.—Dr. Augustus Caillé, of this city, writes that the report of a collective investigation on infantile scurvy in North America, sent us by the recorder of the Pediatric Society and published on July 2d, should, according to a vote of the society, have contained the minority as well as the majority report. The former was as follows: "1. From a study of three hundred and seventy-nine cases of scurvy collected, and taking into consideration certain well-known facts regarding the disease, scurvy appears to be a chronic ptomain poisoning due to the absorption of toxins. 2. It follows the prolonged use of improper food, and abnormal intestinal fermentation is a predisposing factor. 3. Sterilizing, pasteurizing, or cooking of milk food is not *per se* responsible for the scurvy condition. 4. A change of food and the administration of fruit juice and treatment of any underlying cause is the rational therapeutic procedure in scurvy.

[Signed] "Augustus Caillé, M.D.,
"*Member of Scurvy Investigation Committee.*"

Section Officers of the American Medical Association.—The following are the officers of sections, elected at the Denver meeting in June last: *Practice of Medicine*, Frank Billings, president, Chicago; Carroll E. Edson, secretary, Denver. *Surgery and Anatomy*, W. J. Mayo, president, Rochester, Minn.; M. L. Harris, secretary, Chicago. *Diseases of Children*, Henry E. Tuley, president, Louisville; J. L. Booker, secretary, St. Louis. *Obstetrics and Gynæcology*, A. H. Cordier, president, Kansas City; W. D. Haggard, Jr., secretary, Nashville. *Materia Medica and Therapeutics*, Hunt Stuckey, president, Louisville; Leon Solomon, secretary, Louisville. *Cutaneous Medicine and Surgery*, W. T. Corlett, president, Cleveland; J. M. Blaine, secretary, Denver. *Physiology and Dietetics*, J. Weir, Jr., president, Owensboro; Lee Kahn, secretary, Leadville. *Ophthalmology*, Casey A. Wood, president, Chicago; A. H. Williams, secretary, Boston. *Laryngology and Otology*, B. A. Randall, president, Philadelphia; Emanuel Mayer, secretary, New York. *Stomatology*, George V. I. Brown, president, Milwaukee; Eugene S. Talbot, secretary, Chicago. *State Medicine*, Arthur R. Reynolds, president, Chicago; William P. Munn, secretary, Denver.

The Health of the Pope.—A dispatch to *The Sun* from London says that the European governments have been advised that the Pope's health is now so precarious that a fatal termination may come at any moment; this despite the fact that his Holiness continues to transact business and receive important visitors. His recent trouble has been weakness of the heart and poor circulation. It is now complicated by a peculiarly obstinate intestinal catarrh. Dr. Lapponi, the Pope's private physician, recently called in consultation Professor Marchiafava, and it was agreed that the condition of the illustrious patient was most critical.

Hebrew Students in Moscow.—The minister of public instruction in Russia has ordered that the number of Jewish students admitted to the University of Moscow shall not exceed three per cent. of the entire number of students in any one faculty. The Moscow *News* states that only thirty Jewish students will be admitted to the university in the autumn, of which number there will be room for but seven in the medical department.

A Plague Congress.—The Bombay Medical and Physical Society, at a recent meeting, discussed a proposal, originating with Dr. Thomas Blaney, to hold a congress at Bombay in the early part of the coming cold weather for the full consideration of all matters connected with plague. The *Indian Medical Gazette* says that in the records of the society are many old papers of the highest interest bearing on the plague epidemics in India in the early years of the century, and it is, therefore, most fitting that those records should now include an accurate exposition of modern knowledge of the disease, and the experiences of those whose task it has been to deal with it in the last two years.

Poison Ivy in the Parks.—Several cases of rhus poisoning have occurred among children frequenting the parks of this city, and inquiry reveals the fact that poison ivy grows in profusion in many of the less frequented parts of Riverside, Central, and others of the larger parks. The park gardeners say that it is almost an impossibility to eradicate the vine and that the most they can do is to cut down to the ground any plants discovered.

Dr. Friedrich v. Zenker died recently at Erlangen at the age of seventy-three years. Since 1862 he had occupied the chair of State medicine at Erlangen. In 1860 he discovered the presence of trichinæ in the muscles in trichinosis in man, thus demonstrating the nature of the disease.

The Plague in Africa.—In a lecture on the plague, delivered in Berlin on July 7th, Dr. Koch said that he had discovered a hitherto unrecognized endemic centre of the disease in West Africa. During his recent visit he learned of a very fatal disease prevailing in the Hinterland of German West Africa, and on bacteriological investigation satisfied himself that it was the bubonic plague. The mortality attending the outbreak studied by him was ninety per cent. Monkeys and rats also suffered from the disease. Koch believed that there was greater danger of the plague invading Europe than was generally supposed. There are now four recognized endemic centres of the disease, namely, Thibet, Hunan in China, the west coast of Arabia, and Kissiba in West Africa.

An Irish Hospital in Brooklyn.—Steps have been taken by the Ancient Order of Hibernians of Brooklyn to raise a fund of $100,000 with which to build an Irish hospital in that borough. The members of all the Irish societies in Brooklyn are to be invited to contribute, and a number of entertainments will be given, from the proceeds of which it is hoped the fund will be enriched.

St. John's Guild.—The floating hospital of St. John's Guild made its first excursion of the season on July 6th. About four hundred and fifty mothers and babies were taken to the seaside hospital of the guild on Staten Island, and returned in the evening.

Individual Communion Cups.—It is stated that over one thousand sets of individual communion cups were sold to about three hundred churches in this country during 1897. Each service consists of a tray and forty small cups or glasses, holding each about half an ounce.

The Portuguese Red Cross.—The vice-president of the American National Red Cross Society has received a generous contribution from Lisbon, sent by the Portuguese branch of the organization for use in Cuba.

Yellow Fever Checked.—The threatening epidemic of yellow fever at McHenry, Miss., has been arrested by prompt action of the sanitary authorities. Official advices state that the disease there has been stamped out and there is believed to be not one case in the entire country.

A Hospital Train in Collision.—The hospital train bearing two hundred and twenty-three wounded from Tampa to Fort McPherson, in Georgia, met with an accident on the night of July 10th. It was in a rear-end collision with another train, but, while one of the cars was badly broken, fortunately no one was injured.

Typhoid Fever in Camp.—There were forty-one cases of typhoid fever at Camp Alger between May 29th and July 10th, but most of them were imported and there is no fear of an epidemic. The water in the wells of the camp has been tested and found free from any contamination.

The Losses at Santiago.—A report sent to the war department on July 6th by General Shafter states that twenty-three officers and two hundred and eight men were killed and eighty officers and twelve hundred and three privates wounded during the fighting before Santiago on July 1st and 2d. The missing numbered eighty-one. The wounds are said to be of a less dangerous character than usual, only ten or twelve amputations having been needed among the large number of wounded. The rainy season has set in with full force, and our men are constantly wet. There have been some cases of tropical fever, and also a few of yellow fever at Juraguacito, or Siboney.

Red Cross in Hawaii.—The call of the first Manila expedition at Honolulu suggested to some of the residents of that city the advisability of establishing there a branch of the Red Cross Society. Accordingly a meeting was called and a society formed, with Mrs. Sewall, the wife of the American minister, as president; Mrs. Dole, the wife of the president of Hawaii, as vice-president; and Mrs. Emily Foster Day as secretary. Permission was asked and has been granted to use the emblem of the Red Cross, and the society has received official recognition as an auxiliary of the American National Association.

Statistics of the Antitoxin Treatment of Diphtheria.—From a recently published statement of the London metropolitan asylums board we learn that since the introduction of antitoxin in the treatment of diphtheria the mortality in the hospitals under this board's jurisdiction had fallen from 29.3 per cent. during 1894 to 17.7 per cent. during 1897, and there had also been a notable decrease in the mortality among cases of postscarlatinal diphtheria in the convalescent hospitals.

Ice Water on Ferryboats.—The board of health has received many complaints of late about the lack of drinking-water on ferryboats which ply between this borough, Long Island City, and Brooklyn, and it has accordingly passed a resolution that all ferryboats must be provided with ice water for passengers.

The Association of Life-Insurance Medical Directors was in session during the past week in Montreal, under the presidency of Dr. Pabb, of Richmond, Va.

Additional Red Cross Nurses for Cuba.—On July 8th, a party consisting of two surgeons, twenty-four trained nurses, four female and six male assistants, left this city for Tampa. They were sent by the Red Cross Society, and will be forwarded to Santiago as soon as possible after their arrival. The party which left New York a week earlier is already at work among the wounded in Cuba.

Aid to Dispensaries in Baltimore.—The city authorities in Baltimore have cut off appropriations to all dispensaries connected with medical schools, and have increased the appropriations to all independent dispensaries.

Maryland Medical Examinations.—About seventy young physicians presented themselves for examination before the board of medical examiners of Maryland during the semiannual examinations held in May. Out of this number about fifty passed.

A Study of Heatstroke.—A collective investigation into the nature and causes of insolation has been undertaken by the National Academy of Medicine of Brazil. The following are the points concerning which inquiry is being made: 1. Have you observed attacks of insolation, and, if so, do you attribute them exclusively to the atmospheric temperature independently of all malarial influence? If the answer is yes, in what countries and with what summer temperature? 2. Do you know the frequency of such attacks among the engineers and stokers on board steamers? 3. Do the cases of heatstroke which you have observed manifest themselves by the same symptoms as sunstroke? 4. Do cases of direct insolation usually take the hyperpyretic form?

Sandow, the strong man, whose face and muscles have been made familiar to us by advertisements of tonics, strengtheners, and "blood medicines," has opened a school of physical culture in an English provincial town, and advertises to cure dyspepsia and indigestion, while guaranteeing an increase of three inches in the chest measure and a corresponding reduction in the size of the waist.

An English Quack, who has offered a large stock of his alleged specifics to the army medical department, is accused by the music-hall jokers of being a Spanish agent sworn to compass the death of our troopers.

Wholesale Ice-Cream Poisoning.—Forty persons, most of them children, died two weeks ago in Antwerp after eating ice cream at a street stand. The symptoms were those of an irritant poison rather than of ptomain poisoning, and an investigation is to be made.

Twelfth French Surgical Congress.—The twelfth annual meeting of the Association Française de Chirurgie will be held in Paris, in the hall of the Faculté de Médecine, on October 17–22, 1898, under the presidency of Professor LeDentu. Two subjects are announced for set discussion, namely, "Nephrotomy," to be opened by Drs. Guyon and Albarran, and the "Treatment of Goitre," to be opened by Dr. Reverdin, of Geneva. The secretary-general of the congress, to whom all inquiries should be addressed, is Dr. Lucien Picqué, rue de l'Isly, 8, Paris.

Medical Practice in Canada.—A movement is on foot across the border, looking to uniformity in medical laws, so that a license to practise medicine in one province of the dominion will confer the same right in all the others. At present the same annoying restrictions exist there as in this country, with the result that a man who has practised long enough in one place to forget the book knowledge of his student days is practically debarred from going to another province because of the necessity he will then be under to submit to another examination.

The Tuberculosis Committee. — The tuberculosis committee of the State board of health has great difficulty in securing sufficient funds with which to carry on its investigations and to free the State of tuberculous cattle. In 1896 the committee had $20,000; in 1897, nothing, as the governor vetoed the $15,000 allotted in the supply bill, on the ground that it was "inadvisable." In 1898 the committee asked for $50,000, but the finance committees in the legislature cut the item to $10,000, which the governor signed. The secretary of the board says that this amount is barely enough to pay the expenses of the committee and to carry on the education of the farmers in the way of improving the condition and health of their stock by cleanliness, proper care, etc.; also that it would require fully $1,000,000 to clear the State of tuberculous cattle now within its borders.—*Albany Medical Annals.*

In Germany a medical officer is now attached to the primary schools. His duties are much the same as those of our New York school inspectors, but, in addition, every fifth day he is expected to give medical or hygienic instruction.

Lunacy Commission of Maryland.—Dr. George J. Preston, of Baltimore, has been elected secretary to the State lunacy commission, to fill the vacancy created by the death of Dr. William T. Lee. For the past ten years Dr. Preston has been professor of nervous diseases at the College of Physicians and Surgeons.

The Fellows Prize of the New Jersey Medical Society was this year awarded to Dr. Frederick Randolph Bailey, of Elizabeth, for an essay on "The New Histology and Pathology of the Central Nervous System."

The New York Post-Graduate Hospital. — The special committee of the State board of charities, appointed to investigate charges against the New York Post-Graduate Medical School and Hospital, has made a report in favor of the hospital. The charges that money given for the endowment of beds had been misapplied, and that the city of New York had paid for children who had never been in the institution, were not sustained.

The Health of New York.—The report of Dr. Roger S. Tracy, registrar of records, to the board of health, shows a very satisfactory sanitary condition for the first six months of this year. A comparison of the deaths in the boroughs of Manhattan and the Bronx with the deaths for the corresponding period of 1897 gives the following results: The total deaths in 1898 were 19,113 against 19,509 in 1897, showing a decrease of 396 deaths and a death rate of 19.66 in 1898 on an estimated population of 2,048,830, against 19.60 in 1897 on an estimated population of 1,990,562, and being lower than the number of deaths in the corresponding months of any previous year since 1886. The deaths of children under five years of age, perhaps the best test of sanitary conditions, numbered 7,041 in 1896, as compared with 7,238 in 1897, a decrease of 197, notwithstanding the increase of population. The deaths and death rates from the principal contagious and infectious diseases for a period of ten years are given in the following tables:

	Deaths.									
	1889	1890	1891	1892	1893	1894	1895	1896	1897	1898
Diphtheria and croup	1,542	1,014	965	1,131	1,281	1,771	1,146	1,056	980	548
Measles	395	451	480	621	197	495	480	580	204	358
Scarlet fever	1,126	251	749	785	430	380	369	277	300	407
Small-pox	1	2	3	36	48	116	8	1	21	
Typhoid fever	117	96	96	122	136	93	91	83	86	72
Typhus fever	....	....	....	40	193					
Total	3,181	1,814	2,293	2,735	2,285	2,864	2,094	1,997	1,591	1,385

	Death Rates per 1,000.									
	1889	1890	1891	1892	1893	1894	1895	1896	1897	1898
Diphtheria and croup	1.07	1.26	1.16	1.35	1.46	1.96	1.22	1.09	0.98	0.53
Measles	0.50	0.56	0.58	0.7	0.22	0.55	0.51	0.60	0.21	0.35
Scarlet fever	1.44	0.31	0.90	0.92	0.49	0.43	0.39	0.29	0.30	0.40
Small-pox	0.001	0.002	0.002	0.04	0.05	0.13	0.009	0.001	0.02	
Typhoid fever	0.15	0.13	0.13	0.14	0.16	0.10	0.10	0.09	0.09	0.07
Typhus fever	....	....	....	4.03	0.22					
Total	4.06	2.26	2.76	3.23	2.60	3.17	2.23	2.07	1.60	1.35

It will be noticed that the decrease in deaths from diphtheria and croup alone in 1898, as compared with 1897, amounts to 432, nearly 45 per cent., the total number of deaths from these diseases being the lowest, not only relatively but absolutely, since 1872, twenty-six years ago, a decrease which cannot be attributed, Dr. Tracy says, to the waning of a cycle of morbidity, but can be accounted for only by the improvement in the methods of sanitary control, of which the chief are the use of antitoxin and the medical inspection of schools.

Asepsis in Military Surgery.—A medical report sent to Surgeon-General Van Reypen of the navy says that among the wounded sailors and marines about Santiago de Cuba, although in some cases there was considerable laceration, there has been no instance of elevation of temperature of more than a degree above the normal and none of the wounds has suppurated. In similar strain was the report of Dr. Harvey, who returned from Santiago de Cuba on the *Cherokee*. He reported that, although the number of wounded soldiers was large, the character of the wounds was as a rule not serious. The medical corps had met with most gratifying success in treating the wounded, and perfect asepsis had been secured in nearly every case. Few amputations were necessary.

Another Sneak Thief Victimizing New York Doctors.—A woman of slight build and medium height, dressed in mourning, calls to see the doctor, who treated her husband and little girl two and one-half years ago. She is a glib talker and tells the servant that husband and girl are both dead. She states that the doctor wouldn't know her now, for she was then quite stout; she lives out of town at present, and is quite timid about coming to the city alone. She has a sore throat and coughs continually, and asks the girl kindly to bring her a glass of ice water. When the maid returns the would-be patient is gone. The doctor, when he returns, misses a sheet of postage stamps from his desk drawer, an umbrella from the hatrack in the hall, etc.

A New Tuberculin.—Drs. F. Raymond and P. Ravant, in a report to the Society of Biology of Paris on May 28th, stated that bacilli of the tuberculosis of fish, discovered by Dubard, had been cultivated by them in bouillon containing glucose and glycerin, and that on filtering these cultures through porcelain they obtained a toxin which by its smell and its biological reactions exactly resembled the tuberculin derived from the bacillus of tuberculosis occurring in the human subject. With this new toxin they made experiments in two series as follows: First, a tuberculous guinea-pig was inoculated with the toxin, the result being the production of pyrexial reaction with shivering and prostration lasting for six hours, although neither the control guinea-pig nor even the tuberculous guinea-pig which had received control injections of glycerinated bouillon showed any pyrexial reaction. Secondly, two guinea-pigs which had been inoculated on different dates with the bacillus of fish tuberculosis, and which exhibited some emaciation, were injected with half a cubic centimetre of ordinary tuberculin. They both showed a well-marked pyrexial reaction, amounting in the first to 2° C., and in the second to 1.5° C.

In England the journals continue to report deaths under chloroform, and the suggestion is made by the *Medical Press* that in the case of children the written consent of parents be obtained before anæsthesia. The same journal very pertinently asks: "If these deaths are preventable [as recently claimed by the Medical Record, when proper methods of administration are employed] why are they not prevented?"

Society Reports.

THE MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Thirty-Second Annual Meeting.

Held in the Auditorium, Asbury Park, N. J., June 28, 29, and 30, 1898.

DAVID C. ENGLISH, M.D., OF NEW BRUNSWICK, PRESIDENT.

First Day—Tuesday, June 28th.

Epileptic Colony in New Jersey.—DR. T. J. SMITH, speaking in behalf of the committee on the president's address of last year, said that the committee had carried out all its instructions, and had succeeded in having the legislature pass the bill drawn up by it, and appropriate $15,000 for the establishment of an epileptic colony in New Jersey.

Bovine Tuberculosis.— DR. J. W. STICKLER, of Orange, chairman of the committee having this matter in charge, stated that as a result of a conference with the tuberculosis commission and a study of the work that it was doing, the committee felt that it could best further the cause by recommending co-operation with this commission. The society indorsed this recommendation.

Honorary Membership.—DR. SAMUEL HAYES PENNINGTON, on this the fiftieth anniversary of his presidency of the society, was elected an honorary member, and a telegram of congratulation was sent to him.

Annual Address of the President: Patriotism in the Medical Profession.— DR. DAVID C. ENGLISH, of New Brunswick, delivered the address. He said that the Medical Society of New Jersey was the oldest medical society in the country, and that it was founded with the threefold object in view, of "mutual improvement, advancement of the profession, and the promotion of the public good." Dr. Nathan Scudder, of Freehold, who was one of the founders of the society, was also one of the patriot leaders in the effort to throw off the tyranny of Great Britain. Many of the former presidents had taken an active and notable part in the war of the revolution. So far as could be ascertained, only five of the members, three of them clergymen, espoused the British cause. Some idea of the extent to which the society was personally interested in this strife might be gained from the statement in the minutes for 1782 that, as most of the members of the society were actively engaged in the war, no regular annual meetings were held for the years 1775–81. Of the fifty-six signers of the Declaration of Independence, five were members of the medical profession. They were honest legislators, and were not of those who "sold their birthright for a mess of pottage." Yet it should not be inferred that the physicians of New Jersey were to-day lacking in patriotism, or shrank when their country called; still fresh in mind was the death of Dr. John Blair Gibbs, formerly of New Brunswick, a descendant of celebrated patriots, who was the first of the profession to fall in the present war with Spain. The New Jersey patriots of old were made of that kind of stuff so well represented by the farmer boy who, in reply to the query, "Who's looking after the farm?" said, "Father's fighting, I'm digging, and mother's praying." The speaker then considered the patriotism manifested by the profession in time of peace. Here, he said, it found its noblest exemplification; it should not be forgotten that there was a good deal of heroism in every-day medical practice. Nearly all the work of the Medical Society of New Jersey had been for the public good, often against the pecuniary advantage of its members. Thus after twenty-seven years it had succeeded in securing a State board of health; after another long struggle, State hospitals for the insane had been established; efforts, more or less successful, had been made to control the spread of bovine tuberculosis and purulent conjunctivitis in the newborn, and the preliminary steps had been taken toward the formation of an epileptic colony in New Jersey. Surely these were incontestable proofs that the society had been true to the aim of its founders, to labor for the public weal. But the mortuary statistics in connection with the preventable diseases added still more reassuring testimony on this point. In 1888 there was one death from the preventable diseases in every 128 of the population, whereas in 1897 there was only one death to 186.82 of the population. This meant that 4,329 lives were saved in 1897 that would have been sacrificed if the former rate had still obtained. According to a very conservative estimate, this would represent a saving in money during that year of $3,386,620. Dr. English then went on to speak of the part played by physicians in the political life of the country. He deplored their lack of interest in such matters in the past half-century, for, he said, if there had been more physicians in our legislative halls there would be less extreme partisanship and cleaner politics. But it should ever be borne in mind that, as the strength of the republic was to be found in the internal workings of its homes, there was ever a great and glorious field in which the family physician might display the truest patriotism.

Progress in State Medicine and Hygiene. — DR. HENRY MITCHELL, of Asbury Park, presented the report on this subject. He said that 600,000 persons now reached the age of twenty-one years who, sixty years ago, died. The total number of deaths from the chief preventable diseases in New Jersey in the past ten years was 143,472, or a yearly average of 14,347. There was a saving last year of 920 lives. Regarding the disposal of sewage, he said that there was reason to believe that the biological treatment of sewage would be found superior to any other method. Modern investigation seemed to show that sewer-gas was incapable of spreading typhoid fever. Sewer-gas poisoning could, however, lower the resisting power of the human system, and so make it an easy prey to the specific germ of typhoid fever. It was now claimed that the pathogenic germ of acute articular rheumatism had been discovered, and that its inoculation into animals had given rise to endocarditis. Much attention, of late, had been given to the hygiene of the barber shop. The following rules should be observed: (1) The barber's hands should be carefully cleansed; (2) the soap paste should be applied with the hands to the face; (3) only sterilized razors should be employed, and they should be taken directly from a sterilizing-oven; (4) the use of sponges, puffs, pads, and magnesia cakes should be avoided; (5) metal combs should be used. Rutgers College, the speaker said, had taken a most important step in advance of other institutions, in that it now issued certificates of capability to deserving sanitary inspectors.

Progress in Medicine and Therapeutics.— DR. WILLIAM H. ISZARD, of Camden, read the report. He said that twenty-five years ago the specialist was rarely seen, and was looked upon as a quack; now almost every ill was supposed to require the attention of a "specialist," thus leaving very little for the general practitioner. This was specialism run riot. Formerly diphtheria was treated successfully with nitrate of silver; now much valuable time was wasted in waiting for a bacteriological diagnosis or in securing some special brand of antitoxin. The great evil of the present day, in the therapeutic world, was too much experimentation with too many new remedies.

Progress in Surgery.—DR. CHARLES YOUNG, of Newark, read the report.

Appendicitis.—Regarding appendicitis, he quoted the statistics of Dr. G. E. Armstrong, presented at the Montreal meeting of the British Medical Association in 1897. In 517 cases treated in three general hospitals in Montreal since 1889, the mortality was 12.8 per cent. Of this number, 389 were operated upon. Of the 128 non-operative cases, 4 were fatal, or a mortality of 3.12 per cent., from septic peritonitis. Of the 389 operative cases, 84 were "interval" cases, and had no mortality; while of the 305 operated on in the acute stage, 63 were fatal, thus giving a mortality of 20.65 per cent. His working rule, he said, was to operate in all well-marked cases at once, including all cases in which there were pain, tenderness, muscular rigidity with vomiting, elevation of temperature, acceleration of pulse, and anxious facial expression. The operation was usually done after thirty-six or forty-eight hours, unless it was evident that the patient was distinctly improving.

Lateral Curvature of the Spine.— Reference was made to Mr. Roth's report of 1,000 cases of lateral curvature treated by him by posture and exercises, with the result that 869 patients were much improved, and 75 improved. The result was confirmed in 207 of the cases by examination made three years afterward.

Nerve Suture.—A case was reported of paralysis of the musculo-spiral nerve, in which the function had been restored by the successful suture of the musculospiral to the median nerve.

Tetanus Antitoxin.—Mention was made of 3 reported cases of severe tetanus successfully treated with tetanus antitoxin. Out of a total of 36 recorded cases, only 3 ended fatally.

Contagion of Syphilis.—Regarding the contagion of syphilis, it was stated that the duration was difficult to determine, but it was usually longer than was commonly believed. As long as there were any papular exudative manifestations contagion certainly existed.

Splenectomy for Injury.—In 160 recorded cases of splenectomy for various reasons, the mortality was 86 per cent. In 28 cases the spleen was ruptured and prolapsed into the wound, and here the operation was successful. There were only 6 cases in which the operation was done for rupture without external wound, and 5 of these were fatal.

Backward Dislocation of the Thumb.—Mr. Jonathan Hutchinson was quoted as saying that in backward dislocation of the first thumb phalanx a careful trial should be given to the manipulative method described by Farabuff and others. If this failed, a tenotome should be inserted behind the projecting phalanx, no palmar incision being made. The obstacle to reduction was usually found in the glenoid fibro-cartilage and in the sesamoid bone on each side.

Bone Implantation after Trephining.—A case was cited in which trephining had been done on an epileptic in 1896. The seizures ceased for a few months only. Subsequently it was discovered that two spots about the scar were very tender, and pressure upon them precipitated an epileptic seizure. The wound being reopened, the dura mater was found covered with a mosaic of bone fragments. Those fragments which were causing pressure on the dura were removed, and the patient made a complete recovery.

A Splint for Use after Amputation of the Breast.—The author stated that a London surgeon had recommended the use of a rectangular wire splint, as a dressing, after amputation of the breast. A surgeon in Halifax subsequently modified this by suggesting the use of a pillowcase, in which the arm was confined and suspended from the head of the bed.

Blunt-Dissection Operation for Inspection of the Kidney.—According to the speaker, Mr. Robson had recommended an incision beginning to the inner side of the anterior superior spine of the ilium, and carried backward obliquely to the tip of the last rib. The fibres of the oblique, and its aponeurosis, were then split and retracted, exposing the internal oblique, the muscular fasciculi of which were split between the ninth intercostal cartilage and the posterior superior spine of the ilium. When the fingers were pushed in, the fibres of the transversalis were separated. The transversalis fascia was next exposed, and after that the peritoneal fat. At the time of proposing this operation, he was not aware that it had been done previously by Dr. Robert Abbe, of New York. The advantages claimed were: no weakening of the abdominal wall, no division of nerves, no hemorrhage, rapidity of operating, diminution of shock and of the period of convalescence.

Progress in Diseases of the Nose and Throat.—Dr. F. Fayette Smith presented this report. He said that a number of recent papers had appeared, detailing remarkable results from operations on laryngeal cancer, both by the external and internal methods. With the exception of intubation, they showed the greatest advance made in recent years in laryngeal surgery.

Adenoids and Deaf-Mutism.—One observer had reported that he found adenoids in fifty-nine per cent. of the deaf-mutes examined by him, and concluded that such a remarkable percentage indicated some definite relation between the two conditions. The speaker thought it probable that, if due attention was paid to the existence of adenoids in early infancy, the number of deaf-mutes might in time be very materially reduced.

Diphtheria Antitoxin and Ozæna.—According to the reports of Dr. Van der Poel, of New York, and Dr. Moore, of London, the fetor very quickly disappeared after injections of antitoxin. The treatment was said to be inconvenient and not without risk, but the results were considered to be so positive and valuable as to warrant further trial of the method.

Conservatism in Nasal Surgery.—It was pleasing to note the reaction that had recently taken place in favor of greater conservatism in the surgery of the nose. One of many indications of this was to be found in Dr. Delavan's recommendation of submucous operations, with the idea of saving the mucous membrane.

Second Day—Wednesday, June 29th.

Progress in Bacteriology.—Dr. B. Meade Bolton, of Princeton, presented this report.

Diphtheria.—The author stated that all recent articles tended to add to the vast amount of testimony already accumulated, regarding the efficacy of the antitoxin treatment of diphtheria. The statistics for all German cities having a population of over fifteen thousand showed very strikingly the diminution in the ravages in this disease since the introduction of the antitoxin treatment. Just prior to its adoption, the mortality had been nearly fifty per cent.; since then, in a nearly equal number of cases, the mortality had been reduced to sixteen per cent.—a reduction of thirty-four per cent. The tendency now was to use a stronger antitoxic serum, obtained either by evaporation or by using a more potent antitoxin.

Tuberculosis.—In collecting specimens of tuberculous sputum for laboratory examination, it was recommended that the patient should gargle the throat in the morning before saving the sputum. The danger of disseminating the disease lay, not in the sputum becoming dried and being taken up into the air, but in the particles which were moist and were coughed into the air. This had been shown by making animals inhale dust impregnated with dried tubercle bacilli and comparing the results with those obtained by making animals inhale air into which the sputum had been sprayed. In the first series of experiments the animals

contracted the disease with great difficulty; in the second the animals, almost without exception, developed tuberculosis. Rabinovitch had shown that an organism very closely resembling the tubercle bacillus of man in its staining properties was very frequently present in butter. Again, Theobald Smith, a recognized authority in his particular field, had recently shown that bovine tubercle bacilli were not identical with the tubercle bacilli of man. Rabinovitch, working in Koch's laboratory, did not find any genuine tubercle bacilli in eighty samples of butter.

Antituberculous Serum.—It was stated that it was impossible to obtain this serum from horses, as these animals invariably died from even small doses of the tubercle bacilli. The clinical results from the use of this serum were, moreover, not encouraging. The speaker said that his own experiments on animals in this direction showed decidedly that their death was hastened by the treatment. The animals died sooner than those inoculated with cultures of tubercle bacilli or tuberculous sputum.

Immunity.—Koch had pointed out the complexity of the subject of immunity in certain diseases. In tetanus, he had said, immunity might be produced by gradually increasing quantities of a liquid tetanus-bacillus culture. The tetanus bacilli grew abundantly in the animal, curiously enough, although the animal did not contract the disease at all. The animal was, therefore, rendered immune only to the products of the bacilli. On the other hand, in cholera and in typhoid fever it had been shown that by using solid cultures —the bodies of the bacilli—animals might be made to resist the growth of the bacteria. But if the bacilli were made to grow outside of the body, it would be found that when their products were injected into these animals the latter quickly developed the disease, exhibiting no evidence of protection from the products of the bacilli. Koch's idea, therefore, of immunity was that the body must be protected, not alone from the injurious products of bacterial activity, but against the growth of the organisms themselves.

Typhoid Fever.—Regarding this disease, Dr. Bolton said that, on the whole, Widal's test had proved useful and reliable, but it must always be conducted with great care in order to secure trustworthy results. As Pfeiffer was the first one to call attention to this reaction, it seemed but just that his name, instead of Widal's, should be associated with it.

Antistreptococcus Serum.—The experience of the past year with this serum had not been encouraging, and it was probable that it would be gradually abandoned.

Rinderpest.—Koch's investigations on this subject were very interesting and important. He found that by inoculating healthy cattle with ten cubic centimetres of bile obtained from an animal dead of rinderpest, an immunity lasting from forty to sixty days was produced. The finding of an infective agent in the bile was a new observation, and might lead to important results. The same observation had been made regarding the venom of snakes. The bile of the cobra had no potency in combating the poison of other snakes, showing the specific nature of the venom. The same was true of other snakes.

Tetanus Antitoxin.—One veterinary surgeon had reported one hundred and fifteen cases of tetanus in horses, with ten per cent. of recoveries before the use of tetanus antitoxin; since its adoption, sixty-five per cent. had recovered. In one locality in Paris it had become the practice among the veterinarians to administer a prophylactic dose of tetanus antitoxin, and since this had been the rule, tetanus, which was formerly very common, had become almost unknown after operations on animals.

Leprosy.—Opinion seemed still to be divided regarding the efficacy of serum therapy in leprosy.

Bubonic Plague.—In this disease the antitoxic treatment had shown itself to be of great value.

The Umbilical Cord.—Dr. William Pierson, of Orange, contributed an essay with this title, which, in his absence, was read by Dr. Skinner. The author stated that there were still many excellent authorities who claimed that the non-ligation treatment of the umbilical cord had many advantages. The cord was torn through roughly, and after a few drops the blood ceased to escape. On the other hand, there did not seem to be any great objection to ligating the cord, and it avoided many needless alarms. Hippocrates advised against tying the cord until the infant had cried or sneezed, and it was the common rule at the present time not to tie it until the child had cried. According to some observers, the infant received about three ounces more blood if ligation was deferred until the pulsation of the funis had ceased. His personal preference was for a narrow linen bobbin, thoroughly sterilized, for the ligature. The silk ligature was apt to injure the vessels unless great care was used in its application. Catgut was absorbed too rapidly. Many obstetricians of the present day advised leaving a stump about two inches long, on the following grounds: (1) It avoided the possibility of tying a loop of intestine descended into a pouch of the funis; and (2) it left room for the application of a second ligature should hemorrhage occur. The advantages of the short stump were (1) less dead tissue and less fetor, and (2) the greater protection afforded the stump from manipulation and from the movements of the child. His personal preference was for a short stump. The natural process was for the stump to desiccate and wither. Free exposure to the air favored desiccation, as did also the application of some powder, such as boric acid. The application of a pad over this dressing was considered inadvisable, because it helped to exclude the air. Dr. Pierson was in favor of leaving a stump only half an inch long, and stripping it of some of the gelatin of Wharton, as recommended by Goodell, before the application of the ligature.

The Belly Band.—As to the almost universal custom of applying a belly band, he stated that the supposed advantages of the band were (1) warmth, (2) retention of the dressing of the cord, (3) prevention of umbilical hernia. Warmth could be better secured by a loose knitted shirt. Competent observers had asserted that there was a strong developmental tendency to close the umbilical opening, and that consequently very little artificial encouragement was required. Moreover, it would seem that the application of a tight belly band would tend to compress the contents of the abdomen and so actually favor the production of umbilical hernia. In addition to this, the embarrassment of the movements of the abdominal muscles aided in weakening the abdominal wall.

Peculiarities of the Cord.—He had met with one case in which the cord was over five feet in length, and recently one in which the cord was one and one-half inches in diameter. Before ligation of this enormously thick funis, it was necessary to reduce its diameter by stripping the cord and removing the excess of Wharton's jelly. There was still much obscurity concerning the etiology of knots and twists in the umbilical cord. Coiling of the cord around the neck occurred in about twenty per cent. of cases. The largest number that he had seen in any one case was five. When the coiling seriously interfered with delivery, the cord should be cut between two ligatures, and the child rapidly delivered.

Prolapse.—When prolapse occurred without rupture of the membranes, a safe delivery could often be effected by carefully avoiding all interference, thus

preserving intact as long as possible the membranes. When the membranes ruptured early and the cord prolapsed, the well-known postural treatment should be adopted, and an effort made to retain the cord in position by changing the position of the fœtus or by encouraging the speedy descent of the fœtus.

Report of a Case of Foreign Body in the Œsophagus; Retropharyngeal Œsophagotomy.—Dr. John C. McCoy, of Paterson, presented this report, together with a skiagraph showing the location of the foreign body—a whistle. An incision had been made, at the operation, from the lower border of the cricoid cartilage to the upper margin of the sternum, the sternomastoid being retracted outward and the trachea inward. The œsophagus having been exposed, it was found that the tissues of the latter were much swollen, and at the point where the whistle was lodged they were so eroded that it was evident that further efforts to dislodge the foreign body would have proved dangerous. There was no shock or vomiting after the operation. At first small quantities of sterilized water were administered by the mouth, and subsequently a little sterilized milk was given. A fistulous opening formed, but closed in seven days. The usual rule was to withhold all nourishment by the mouth for twenty-four or forty-eight hours after operation, but he preferred giving small quantities of sterilized water in order to keep the œsophagus clean. His conclusions were as follows: (1) A foreign body impacted in the œsophagus for over twelve hours, particularly if it was known to have sharp edges, demanded immediate removal through an external incision. (2) The prolonged and continued use of œsophageal instruments should be condemned, as the tissues were usually lacerated by them and their vitality was lowered. (3) If the condition of the tissues would admit of it, the wound in the œsophagus should be closed by sutures at the time of the operation.

Report of a Case of Foreign Body in a Bronchus; Tracheotomy.—Dr. Walter B. Johnson, of Paterson, reported this case, which occurred in a girl of a little over three years. The operation was not done as soon as desired, because the parents withheld their consent. Finally, a large incision was made in the trachea, with the idea of stitching the trachea to the skin and leaving an ample opening in case the foreign body could not be found at the time of operation. By a coughing-effort, the foreign body, a large kidney bean, was brought within reach, and was removed with forceps.

Dr. E. J. Ill, of Newark, objected to closing the tracheal wound with sutures, as this sometimes gave rise to dangerous emphysema.

Dr. W. B. Johnson said that the trachea had been completely closed by sutures in Dr. McCoy's case, as well as in his own, and both patients made a good recovery without any untoward symptoms that could be attributed to this procedure.

Dr. Cantwell said that, in an experience comprising about fifty tracheotomies, mostly for membranous croup, he had never sutured the wounds in either the trachea or the skin; he had never observed any emphysema, and the subsequent scar had not been very large.

Dr. Judson Daland, of Philadelphia, thought it would be better to give the œsophagus entire rest for at least twenty-four hours, more especially as the sterilized water given by the mouth must quickly become contaminated with the numerous micro-organisms inhabiting the buccal cavity. He recalled two interesting cases of foreign body in the air passages, and dwelt upon the serious consequences that had been averted in the cases just reported by a prompt resort to operation.

Dr. McCoy replied that it was impossible to give the œsophagus absolute rest, as it must be disturbed from time to time by the swallowing of saliva.

Discussion on Milk as a Culture Medium, and its Capacity for Spreading Infectious Diseases.—Dr. John L. Leal, of Paterson, opened the discussion by a consideration of the special subject of "Milk as a Carrier of Infection." He said that the diseases transmitted by milk were typhoid fever, cholera, tuberculosis, and scarlet fever. After dwelling upon the more common sources of contamination of milk in the dairy and in its transportation, he cited interesting examples of the methods pursued by health authorities in tracing to their source diseases arising from milk contamination.

Dr. Richard C. Newton, of Montclair, continued the discussion. He said that he had insisted last year that the milk of the goat and of the ass might be used with great advantage under certain circumstances. It was now found that skimmed milk could be fed to various animals with good results. For feeding to milch cows, it was recommended to heat the milk to 150° F., mix it with chaff, and allow it to ferment for forty-eight hours. During the past year Koplik had asserted that he had observed a number of cases of milk poisoning following the use of pasteurized milk. It had been recently claimed that the so-called "feed boils" observed on the udders of milch cows when they were first turned out to pasture after having been stall fed through the winter were sources of disease. This had only just been brought to the attention of the health authorities, and no positive statements were yet forthcoming. It had also been claimed that tuberculosis in cows was largely due to overmilking, and it had been recommended that the cows be allowed to go dry for the last three months of gestation. Dr. E. F. Brush believed that the chief, if not the only, source of tuberculosis in the human subject was to be found in tuberculosis in cattle.

Bologna-Sausage Horror.— Dr. Newton spoke of an exceedingly repulsive and dangerous practice that was common even in dairies claiming some degree of respectability, viz., the selling of the bodies of animals dying on the dairy farms to bologna-sausage manufacturers. In his opinion, the testing of all cattle with Koch's tuberculin should be compulsory, and the practice just referred to should be punishable as a misdemeanor.

Dr. J. W. Stickler, of Orange, said that the composition of milk made it a nutritive medium for every germ the biology of which was understood at the present day. According to an investigation conducted in the city of Boston, when healthy cows in a clean dairy were milked into sterilized flasks five hundred and thirty bacteria only were found in a cubic centimetre; but when the milking was done in the usual way and it was received in the common flaring milkpail, there were on an average 30,500 bacteria to every cubic centimetre immediately after the milking. The germs of diphtheria, cholera, and scarlet fever developed at the ordinary room temperature, and did not, as they multiplied, alter the general appearance of the milk. The only exception, perhaps, was that, according to Klein, the germs of cow scarlet fever caused a coagulation of the milk at 35° C. It was important to remember that not only did all known germs develop in milk, but that they were capable of living in it.

Dr. Baldwin spoke of the propriety of having all milk sterilized before being taken into the system.

Dr. Chambers spoke of the good that had been accomplished by the use of "certified milk."

Dr. Hedges gave an instance of the way in which disease might be disseminated through the milk supply by those who had no thought for others and no regard for law or decency.

Method of Administering and Use of Enteroclysms.—Dr. Judson Daland, of Philadelphia, read

an essay on this subject. He preferred to use a rectal tube having rather thick walls, a very smooth surface, and a rounded and slightly tapering tip. It should be two feet long and three-eighths of an inch in diameter, and have a terminal opening. A dark line should be marked on the tube at a distance of eight inches from the tip, to serve as a guide in its introduction. The obstacles met with might be hemorrhoids, tumors of other kinds, a retroverted uterus, displaced ovaries, or ovarian tumors. The knee-chest position would often cause obstructions to fall forward, and thus admit of the easy passage of the tube. The reservoir—a fountain syringe or a funnel—was usually placed at a height of four or five feet. Ordinarily a child received one pint, an adolescent two pints, and an adult three or four pints. As a rule, ten minutes should be occupied in administering the enteroclysms, and the fluid should be retained for a like period. When the patient experienced colicky pain, it was usually due to the presence of gas, to too rapid introduction of the liquid, or to introducing too large a quantity. Sometimes relief and comfort would be afforded by tightly bandaging the abdomen before giving the enteroclysms. These injections could be given at intervals of four hours, or they could be administered daily or on alternate days, according to the object desired to be accomplished. That the liquid frequently passed the ileo-cæcal valve was clearly shown by experiments which he had performed on the bodies of seven children. In four there was no difficulty in causing the fluid to pass through into the small intestine, and even out through the mouth and nose. In two cases the valve prevented irrigation of the small intestine, and in one case the fluid did not pass the ileo-cæcal valve. In several cases of cholera in which frequent enteroclysms of tannic acid were administered, this same solution was vomited.

Dr. Daland mentioned the following conditions as indicative of the chief uses of this therapeutic procedure: (1) In long-standing and obstinate constipation; (2) in auto-intoxications resulting from decomposition of the intestinal contents; (3) in many forms of irregular gout associated with scanty and highly acid urine; (4) in chlorosis, because of the commonly associated fæcal anæmia; (5) in progressive pernicious anæmia without obvious cause; (6) in diabetic coma and uræmic conditions; (7) in cholera, as an important life-saving measure; (8) in typhoid fever, more particularly in the early stages, as a cleansing agent, an antipyretic, and a diuretic; (9) in pseudo-membranous colitis, even of long standing; and (10) in cases of sunstroke.

Dr. R. C. Newton said that this method of treatment should also prove beneficial in cholera infantum and in cases of milk poisoning. The addition of antiseptics, such as chlorine water, seemed to him to open a very wide and important field.

Dr. Hedges, of Plainfield, alluded to the great value of very cold enteroclysms in the treatment of the acute intestinal indigestion of children, particularly when associated with high fever.

Dr. Benjamin, of Camden, spoke of the important aid rendered by ice-cold enemata in controlling intestinal hemorrhage in cases of typhoid fever.

Dr. P. C. Barker, of Morristown, called attention to the benefit to be derived from the use of enteroclysms, alternately of cold and hot water, in the treatment of a common but obstinate disorder—*i.e.*, catarrhal jaundice. He had also used various antiseptics with the enteroclysms—*e.g.*, a 1 to 5,000 solution of bichloride of mercury in dysentery—but, after all, the washing out of the large bowel was the point of greater importance. In his opinion, it would be necessary, in some very large persons, to use a rectal tube nearly four feet in length.

Dr. Daland replied that, owing to the comparatively large quantity of the fluid retained and absorbed, he had been chary in the use of antiseptics. The treatment *par excellence* for Asiatic cholera consisted in the systematic use of enteroclysms of a three-per-cent. solution of tannic acid, as experiments had fully demonstrated that the cholera bacilli could not develop in an acid medium. Enteroclysms were also useful in cholera infantum and cholera morbus. He knew of no better intestinal antiseptic than a sufficient quantity of healthy bile. In cases of catarrhal jaundice little or no bile entered the intestinal tract, and as a result the contents of the bowel putrefied and the resulting toxic products were ordinarily carried back to the liver; hence there was good reason for using enteroclysms in this disorder. He saw no objection to using a longer rectal tube, but ordinarily when it had been inserted eight inches it was beyond the sigmoid flexure, and there seemed no good reason for inserting it farther than sixteen inches, as the tip should then be near the splenic flexure of the colon.

School Hygiene with Reference to the Production of Ocular Disease.—Dr. Walter B. Johnson, of Paterson, read this paper. He said that the percentage of myopics was constantly increasing. The light should be direct, not reflected from adjacent buildings, and all light should enter from the left and behind. It had been advised that the blackboards be tinted green. It was also important that a proper system of ventilation, no matter how costly, should be maintained.

Dr. W. B. Atkinson, of Philadelphia, emphasized the importance of the subject; and Dr. Newton suggested that the best way to begin a reform of this kind was to educate the teachers in matters pertaining to the proper lighting and ventilation of schools.

Chronic Cardiac Disease and its Management.—Dr. Louis Faugères Bishop, of New York, presented a communication with this title, calling attention to the fact that the care of cardiac disease was the care of invalids in general. Many of these patients would have lesions of both the aortic and mitral orifices, but the symptoms of one or the other type would usually be specially prominent. The hypertrophied heart muscle was like an overtrained athlete, and it was because of its tendency to undergo degeneration that marked benefit so often resulted from the judicious use of hydrotherapy and active exercise. Chronic constipation was the arch enemy of persons afflicted with heart disease, and called for constant medical supervision. A good way of overcoming it was to instruct the patient to take a single large dose of the fluid extract of cascara sagrada every night for a month, gradually diminishing the dose so as to secure a daily natural evacuation. At the end of the month an effort should be made systematically to reduce the dose until only a few drops were taken at a time. This very small dose was continued for a while longer for its moral effect. Calomel was undoubtedly valuable in relieving the general congestion, but it never produced the magical results so often claimed for it. The necessary amount of nourishment should be taken in very moderate quantities. It was important to instruct such a patient that death was not likely to come suddenly, and that any disturbance of digestion, loss of color, or evidence of failing nutrition or disordered breathing should be looked upon as an imperative demand for an immediate revision of the whole mode of life.

Dr. John C. Johnson, of Blairstown, said that an occasional small dose of calomel would often very quickly relieve the respiration. Constipation and dilatation of the stomach and colon could be satisfactorily managed by a morning draught of Epsom salts containing two drops of tincture of nux vomica, or by

giving at night a tablet containing rhubard, aloes, and gentian.

Dr. A. W. Rogers, of Paterson, said that he had been disappointed in the action of cascara; the combination of aloin, belladonna, and strychnine was more effective.

Dr. Newton remarked that in obstinate cases of flatulent dyspepsia, when other drugs had failed to give relief, he had found asafœtida very useful.

Uterine Displacements.—Dr. H. B. Costill, of Trenton, presented this paper. He said that the uterus was maintained in its position in the pelvis very largely by intra-abdominal pressure, that anteflexion was very much less common than had been taught, and the symptoms usually ascribed to it were largely the result of uterine stenosis. Thorough dilatation, curettage, and drainage would cure nearly every case of anteflexion. In all cases of retrodisplacement, if the perineum was torn, it must be repaired. The uterus should be restored as nearly as possible to the normal position, and should be retained by suitably medicated tampons, renewed every three days, until the uterus showed a disposition to remain in place, or until it became evident that an operation was demanded. The operation recommended by Dr. Costill was known as "utero-ventral approximation." In this operation the abdomen was opened by a short incision, as low down as possible to avoid injury to the bladder. Adhesions were broken up, the uterus was brought forward, and two sutures of gut were passed through the abdominal wall and tied on the outside. They should remain for about four weeks. The abdominal wound was closed by independent sutures in the usual manner. In the early stages of prolapse, when there was not much descent, curettage of the uterus and amputation of the cervix, with repair of the perineum, should be sufficient. In more advanced cases a plastic operation alone would not prove adequate, for the uterus was not restored to its normal position. Some form of ventral fixation or suspension must be used. The much-abused pessary was capable of accomplishing much good, although the degree of success was largely dependent upon the personal element. The patient, while wearing a pessary, should not be allowed to pass from under observation for longer than a month at a time.

Dr. E. J. Ill said that the displacements that had proved most troublesome in his experience had been the lateral ones, and that form of retroposition resulting from shortening of the utero-sacral ligaments. The former were especially liable to make a woman an invalid. They might be either congenital or acquired, the latter naturally proving more tractable. The cases of retroposition alluded to occurred most often in unmarried or sterile married women, and could be treated by dilatation of the uterus and stretching of the utero-sacral ligaments under anæsthesia. Following a recent suggestion, he had tried in one case the plan of opening the abdomen, cutting the utero-sacral ligaments, and doing ventral fixation. In this instance the procedure had given an exceedingly satisfactory result.

Dr. Charles P. Noble, of Philadelphia, said that, after a large experience with both ventral fixation and the Alexander operation, he had come to the conclusion that the latter gave distinctly better results. In certain cases of retrodisplacement, the fact should not be lost sight of that the displacement was really a secondary matter, the essential feature being disease of the appendages. In this class of cases he advocated extirpation of the appendages and hysterectomy. He fully indorsed the views of Dr. Costill regarding the treatment of procidentia, but favored Kelly's method of doing ventral suspension. While pessaries had a limited sphere of usefulness, it should be remembered that those who had employed them most extensively and scientifically did not claim more than fifteen or twenty per cent. of cures in the most favorable class of cases—*i. e.*, retroversions occurring after labor.

Regression versus Progression: Viewing the General Practitioner from a Scientific Standpoint.—Dr. J. C. Applegate, of Bridgeton, in an address with the above title, deplored the excessive specialism of the time, which he branded as the source of much discontentment among the laity and the cause of much injury to the general practitioner. He also regretted that the work of the physician and the pharmacist was no longer co-operative, and the present slavish adherence to fixed formulæ, as found in compressed tablets.

Dangers of Certain Faulty Impressions Regarding the Menopause.—Dr. Philander A. Harris, of Paterson, read this paper. He said that two-thirds of all women miss their periods for a longer or shorter time before the complete cessation of the menstrual flow. A gradual shortening in the length of the menstrual period and a diminution in the quantity of the flow were observed in those in whom the cessation of menstruation was abrupt. He was convinced that insanity, and especially melancholia, might result from disturbances incident to the menopause. Both leucorrhœa and hemorrhage were often lightly regarded by the patient and her family physician, and a serious condition, such as malignant disease, was consequently neglected for a long time. Cancer of the uterus was usually characterized at first by leucorrhœa and irregular or excessive menstrual flow. After carcinoma came fibromata and myomata as a cause of irregular or excessive hemorrhage. There was little in the change of life itself to effect pronounced pathological conditions in the uterus or vagina.

Dr. C. P. Noble said that one should not expect any greater disturbance at the menopause than at puberty, and, as a matter of fact, the hot flashes and sweatings, and occasionally mental derangements, constituted the chief disturbances observed at the change of life. It was the duty of the family physician to educate his patients to the belief that the menopause should not be accompanied by irregular discharges, and that their occurrence should be an indication for a searching examination for the purpose of detecting the uterine disease of which they were the manifestations. The danger of delay applied chiefly to cases in which there was cancer of the cervix, for cancer of the body of the uterus progressed very slowly and the prognosis was very good, even after the symptoms had lasted two or three years.

Dr. Balleray, of Paterson, spoke of the large percentage of cases that did not reach the surgeon until the operative stage had passed. This was to be explained, in some instances, by negligence on the part of the general practitioner, but often to his dread of referring cases to the gynæcologist, who unfortunately had a reputation for being too ready to operate on slight provocation. Neither side was wholly blameless.

Early Diagnosis and Treatment of Pott's Disease.—Dr. S. A. Twinch, of Newark, read a paper on this subject, illustrating it freely by projecting on a screen photographs from life.

Dr. J. B. Edwards, of Gloucester County, spoke of his personal experience as a sufferer from this disease, and referred most feelingly to the great and good work done by Dr. L. A. Sayre in advocating the plaster-of-Paris jacket as an efficient support for the diseased spine. He considered it the only appliance for this disease.

Dr. I. W. Condict said that he had found the silicate-of-sodium jacket much lighter and more cleanly

than the plaster of Paris. A jacket of this material could be easily made over a plaster-of-Paris jacket, as a cast.

Third Day—Thursday, June 30th.

Cases of Appendicitis.—Dr. John McCoy reported eleven cases of appendical trouble operated upon during the last ten months. From this number, seven specimens had been selected for presentation. Two of the cases showed an extremely short meso-appendix. One case followed a protracted attack of typhoid fever. Pain was present in all but one case. Nausea was present in nine cases. Tympanites was present in only three, and in each of these there were pus in the abdominal cavity and considerable plastic lymph on the intestine. The temperature varied from 99° to 104° F., the most severe case having the lowest temperature. In this case, although the temperature was only 99° F., the pulse was 130 and extremely weak. The case having the temperature of 104° F. had a pulse of 100, and it was of good quality. In only one instance was there a walling-off of the abscess cavity.

Nephrectomy.—Dr. McCoy also presented a kidney removed four weeks ago from a woman upon whom Dr. H. A. Kelly had recently operated for an interstitial fibroid. His patient made a good recovery, leaving the hospital in two weeks.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

NEW HOSPITAL—SUNDAY FUND—ST. THOMAS' HOME—AN EXPERT AID PROPOSAL—LEUKÆMIA—INFLUENCE OF MINERAL CONSTITUENTS OF VEGETABLES ON GOUT—"PHOSSY JAW."

London, June 24, 1898.

The Prince of Wales laid the foundation stone of the new University College Hospital on Tuesday. The fund for rebuilding this hospital was, as you may remember, presented by Sir J. B. Maple, M.P. The sum of £100,000 was the munificent donation for this purpose.

The Hospital Sunday fund, so far as sent in, exceeds £14,000. This is less than last year at the same period, but perhaps the sums yet to be forwarded may make up an average year.

Complaints have now and again been heard as to the management of St. Thomas' Home. Perhaps some have been unfounded. At any rate, they were not sufficiently authenticated to insure inquiry. Now a case has been stated which calls for strict investigation. Greene Pasha has written to *The Scalpel* an account of the manner in which he was treated when wishing to enter the home. The narrative reflects on the manners of the medical officer who failed to keep his appointment with the eminent pasha as well as on other officials. It would appear as if the medical officer could not have known how distinguished a member of the profession he was neglecting to meet with ordinary courtesy. Greene Pasha complained to the governors of St. Thomas' Hospital, but was informed by the secretary that in the opinion of the committee his complaint was not justified. This looks as if they would like to contradict his statement, but they do not venture to do so. I am of opinion that the treatment he has described is a disgrace to the officers concerned, and I am not alone in that opinion. The career of Dr. H. R. Greene, Pasha, should have secured respect, and the fact that he was a sufferer seeking relief and ready to pay all the charges at the home might have sufficed to elicit sympathy for a sick professional veteran. But perhaps the St. Thomas' officers are as ignorant of medical history as they appear to be of the requirements of ordinary good manners.

According to a prospectus sent by post, "a medical expert aid committee" proposes to enable the middle classes to obtain the aid of consultants at reduced fees. Of course clergymen and other non-medical men are ready to assist in the further reduction of the profits of the profession, but it was hardly to be expected that a medical man would be secretary to any such scheme. Dr. H. Woods must know that those who really cannot pay a consultant's fee when their usual attendant needs or wishes a consultation are always able to obtain expert advice. The friendly way in which this is done has always worked well. The favor of a reduced fee on the one hand, and a note to a consultant at his hospital on the other, have hitherto sufficed to meet all cases. Dr. Woods, who has affected an interest in certain medico-political questions, ought to know that a scheme similar to this has previously been proposed, and met with the condemnation of both consulting and general practitioners.

Drs. Rose Bradford and Batty Shaw gave an account of five cases of acute leukæmia before the Medico-Chirurgical Society—two of them dating from 1890, the other three from last year. All came under observation for anæmia with excessive pallor, weakness, swelling, and ulceration of the mucous membrane of the gums, cheeks, or lips, and fever. Some had purpuric patches and some melæna. All ran a rapid and fatal course, the maximum of illness being eight weeks. The lymphatic glands were enlarged in all cases; the spleen in two cases. The blood showed great excess of white corpuscles, mostly due to the presence of large lymphocytes. In two cases these formed over ninety per cent. of all the white cells present. A few myelocytes were present in two cases.

Dr. H. G. Turney mentioned a similar case, in which the blood showed a proportion of white to red as one to fifteen. Dr. Rolleston thought it difficult to distinguish between acute Hodgkins' disease with a terminal lymphocytosis and some of the cases related.

Dr. Norman Moore had seen two cases following malaria and syphilis, acquired in Africa and terminating within a year, but he had seen no case so rapid as those of Drs. Bradford and Shaw.

Dr. A. P. Luff has been extending his researches on the effects of diet on the gouty process. Last year in the Goulstonian lectures he argued that it is of little consequence as regards the production of uric acid from proteid matter whether the proteid introduced be of animal or of vegetable origin. Though this be so, it is well known that different articles of diet exercise a different influence on the precipitation of sodium biurate and on the solution of uratic deposits. He has shown that the saline constituents of animal and vegetable foods differ in their effects on sodium biurate. It appears probable that the mineral constituents of vegetables, if present in the fluids of a gouty patient in sufficient quantity, might delay the advent of an attack by increasing the solubility of the biurate, and by their solvent action on uratic deposits facilitate the removal of these deposits. Dr. Luff has now carried out a long series of experiments on the mineral constituents of all the commonly used vegetables, and last week communicated his results to the Medico-Chirurgical Society. His object was to ascertain the relative effects of the mineral constituents on the solubility of sodium biurate at the temperature of the body, and therefore presumably on uratic deposit, as well as the influence, if any, in retarding the conversion of the quadriurate into the biurate. He experimented with spinach, Brussels sprouts, potatoes, asparagus, Savoy cabbage, French beans, lettuce, beet root, winter cab-

bage, celery, turnip tops, turnips, carrots, cauliflower, sea kale, and green peas. His results are that the minerals of green peas have no influence, but those of all the others appreciably increase the solubility of sodium biurate.

Curiously it was also shown by other experiments that the solvent effect of a vegetable ash has neither a direct nor an inverse relation to the proportions of potassium, sodium, calcium, magnesium, and iron salts present, or to the proportions of phosphates, sulphates, and chlorides. To no one constituent does the solvent effect seem due. The next step was to ascertain whether an artificially prepared ash would act as the natural. Spinach, which has the greatest effect on the biurate, was selected for the trial, and a powder prepared containing the same constituents as the ash of spinach and of precisely the same alkalinity. This product, instead of exercising the solvent action of the natural ash, actually had a deterrent effect on the solubility of the biurate, and that, too, in all proportions. The only explanation of this unexpected result offered by Dr. Luff is that in the natural ash there is some combination of the mineral constituents which cannot be artificially imitated, and on that combination depends the solvent influence. If this be so, the ancient practice of giving vegetable ashes in gout is found to have a scientific basis.

The next point to determine was whether the minerals of vegetables can also delay the conversion of quadriurate into biurate. The results of experiments made with this object show that in some cases the conversion is considerably delayed, especially by spinach, Brussels sprouts, French beans, cabbage, and turnips. It is natural to infer that if such ash constituents were present in suitable proportions in the blood and the excretion of quadriurate was at the same time promoted, the elimination of the quadriurate might be secured without the occurrence of precipitation of biurate into the tissues.

Very different is the effect of the mineral constituents of meat. These, as Dr. Luff has previously shown, diminish the solubility of biurate and delay to a very slight extent the conversion of quadriurate into biurate. He does not maintain that the different effects of animal and vegetable diets depend solely on the mineral constituents. Still to these he thinks we must look for an explanation of the fact that excess in one case tends to produce gout, in the other to retard it.

From all this we may conclude that the vegetables for the gouty are spinach, which is *facile princeps*, Brussels sprouts, French beans, winter cabbage, Savoy cabbage, turnip tops, turnips, and celery.

Bryant & May were fined for not reporting cases of "phossy jaw" recurring in their factory. The medical adviser of the company has naturally been the subject of comments as to his conduct in the matter. The law has been vindicated so far as the fines go, and the inspectors seem to have been wakened up by the prosecution. Two cases have been before the magistrates at Gloucester this week. One was dismissed, as the man had not made known his disease to his employer; in the second case a fine was imposed.

Loss of Half the Brain.—A man is reported by Porta to have lost the whole of his right cerebral hemisphere by an accident. He was unconscious for a few hours only, and when he recovered he proved that immediately after the accident he had not been unconscious, because he recollected being picked up and taken to a hospital. Eighteen months later the wound was closed. He had of course left-side paralysis, but, his left cerebral hemisphere being intact, his intellectual functions are said to have been unimpaired.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE HEALTH OF PARIS—SLIGHT INCREASE IN THE MORTALITY RATE—THE TREATMENT OF "BRAIN FAG"—OUT-DOOR EXERCISE—GAMES AND SHAMPOOING—DANGERS OF VOMITING, DIARRHŒA, AND LEAD POISONING FROM EATING CANNED MEATS—DR. CABANÈS AND SAINTE-BEUVE—DOCTORS IN THE CHAMBER OF DEPUTIES—A NEW TUBERCULIN, ETC.

PARIS, June 25, 1898.

THE health of Paris continues good. In spite of the alternating warm and damp weather with cold winds that we have been having lately, the mortality rate compares very favorably with that of previous seasons. The last weekly *Bulletin Hebdomadaire* of municipal statistics shows for the twenty-third week of 1898 nine hundred and thirty-five deaths—a decrease of three from the preceding week (nine hundred and thirty-eight), but a slight increase above the ordinary average of weeks in June, which is eight hundred and ninety-four. This increase is to be placed chiefly to the account of diseases of the respiratory organs, measles, and infantile diarrhœa, especially the two latter. There is, however, a lowering in the number of deaths from pulmonary phthisis, and it is to be hoped that the prophylactic measures recently discussed and recommended by the Academy of Medicine, which can easily be carried out, not only in hospital and private practice but by the laity as well, will reduce steadily in the future the mortality rate from pulmonary tuberculosis. It will be remembered that the whole question seemed to turn upon the sequestration and disinfection of sputa, which are the real danger in phthisis.

It is not always easy to draw the line between "brain fag" and neurasthenia; that is, between temporary cerebral fatigue and true nervous exhaustion. Usually the two go together. But in those cases in which an intellectual worker is run down without its coming to a case of neurasthenia proper, and such cases can be counted by the thousands in the United States as well as in France, what is best to be done? Dr. Romme has just made some very valuable suggestions with reference to them, and bases justly the whole treatment on hygiene and tonics. Nevertheless the keynote of treatment in all such conditions is rest. Some of Dr. Romme's suggestions are these: The patient should go and live in the open air in the country; if he cannot, he should occupy rooms well aired, ventilated, and with full exposure to the sun. Between each period of work covering a few hours, and especially before and after meals, he should take mild physical exercise in accordance with his tastes, such as walking, bicycling, rowing, gymnastics, open-air games, bowling, golf, croquet, lawn tennis, etc. If he cannot go out, he can do gymnastics in his rooms, play billiards—in a word, seek distraction and movement. If he finds gymnastics too fatiguing, he will derive benefit from carriage exercise. His meals ought be regular and substantial, with avoidance of alcoholic drinks. Massage and douches are valuable adjuvants.

I have found these cases much benefited by shampooing the head every day and then rubbing it with alcohol before drying thoroughly. It is well, however, to begin the treatment with a complete absolute rest from mental labor for several weeks before adopting Dr. Romme's suggestions. Horseback riding is a most valuable exercise and aid to re-establishment in brain fatigue. As regards tonics there is nothing better than a phosphate combination of iron, quinine, and strychnine, alternating with a course of the glycerophosphates.

A subject that may interest the United States commissary department just now is that of canned meats, in order to prevent such mishaps as the one that oc-

curred only a few days ago in a squadron of the third regiment of French cuirassiers in garrison at Tours. Eighty-five of the men were taken with vomiting and diarrhœa after eating canned meat, which incapacitated them for service. It is of course impossible in the distribution of quantities of canned meat to troops not to give out spoiled cans, if such there are. The fault is clearly with the preparers and canners. These processes ought to be superintended directly by a competent person, preferably a physician or health officer; only perfectly pure fresh meat, absolutely sound, being used, and care being taken that the cans are well and smoothly soldered and that there are no little bits of tin or solder around the inner border or adhering to the sides of the can, for lead poisoning is another danger that lurks in canned meats or vegetables. The sealing besides must be hermetical.

The inauguration on Sunday last in the gardens of the Luxembourg Palace of the statue of Sainte-Beuve was an event of much interest to the medical profession, which was largely represented at the ceremony. In fact the subscription for the monument was originally started not by men of letters, of whom Sainte-Beuve was a chief, but by Dr. Cabanès, director of the "Chronique Médicale." Nor should it be forgotten, as was recalled only a few days ago by a distinguished physician, who is also a littérateur, that Sainte-Beuve was during his early youth an "externe" at one of the great Paris hospitals, and that one day at the Hôtel Dieu, where he took the place of an "interne" who was absent, he put on the white apron beside Dupuytren. He, however, soon abandoned the scalpel for the pen, and confined his dissections thenceforward to those of works of the mind. Nevertheless, considering that it was a just pride that such a man had begun life in the ranks of the medical profession and surprised that the illustrious writer had not obtained democratic honors in cold, pale marble on a public place or square, Dr. Cabanès had the happy inspiration of asking his confrères to repair the oversight—with what result it has just been noted. The monument is a pure white marble bust with lifelike smiling expression, resting on a stone plinth. Underneath the bust are a pen and a palm leaf. The simple inscription is: "To Saint-Beuve of the French Academy, 1804–1869. His admirers and friends."

The elections that have just taken place have sent some fifty-seven doctors or health officers to the chamber of deputies.

Dr. Ramond affirms to the Biological Society that with Dr. Ravaud he has obtained by cultivation in glyco-glycerinated bouillon from bacilli of tuberculous fish a tuberculin which by its odor and biological reactions resembles that coming from the bacilli of human tuberculosis. And Dr. Ledoux-Lebard communicates a certain number of experiments tending to establish that from a botanical standpoint the bacilli of tuberculosis in fish may be compared with those of tuberculosis in man and the mammifera.

FOREIGN BODIES IN THE NOSE OR EAR.

To the Editor of the Medical Record.

Sir: In looking over the article of Dr. Barret in the Medical Record of June 11th, and the note by Dr. Winslow in the issue of June 25th, on the removal of foreign bodies from the nose or ear, I was surprised that they failed to mention a simple and very effective instrument which is within every physician's reach, viz., the wire snare.

The loop of a Jarvis or Sajous snare, or a simple piece of stiff fine wire bent into a loop, will slip past a hard, smooth body like a shoe button, a glass bead, or a bean, which completely occludes the auditory canal, and will easily remove it, when any sort of forceps or hook would fail to grasp the object and would very likely do more or less injury in the attempt. The instrument works equally well in the nose, and the ease with which it can be used and the freedom from possible injury, especially in the case of a frightened, struggling child, make it the most desirable means within my knowledge for this class of work.

I would simply add this to the very valuable suggestions contained in the articles above noted, in the hope that it may prove as satisfactory to others as it has to myself.

Frank B. Storer, M.D.

Holley, N. Y.

A SIMPLE METHOD OF PNEUMATIC MASSAGE OF THE TYMPANIC MEMBRANE AND OSSICLES.

To the Editor of the Medical Record.

Sir: In a lately published account of the various forms of apparatus for passive exercise of the drumhead and its attachments, I find none so simple and convenient and so safe for the patient's use as the following, which for twenty years or more I have been wont to improvise in appropriate cases.

Smooth in a flame the ends of an inch of thick glass tubing of proper size. Fit one end to the patient's meatus by a half-inch of rubber tubing slipped over it, and attach to the other end a yard of small rubber tubing. Into this, at its further extremity, slip the point of a straight pipette ("medicine dropper"), whose rubber bulb must be not too large and not too stiff. If the pipette point is too fine, cut it off.

The patient holds the pipette by its glass stem between the thumb and last three fingers, placing his index lightly on the bulb, which he rests on the knee or a table. By a wrist motion in which the finger does not leave the bulb, or the bulb its resting-place, he makes rapid compression and relaxation, and, if the tube is not kinked, the pressure changes are promptly transmitted to the membrane.

If it is desired to treat both ears at once, introduce a Y connecting-tube. I have found a double stethoscope serves the purpose. An electro-motor may replace the hand for office use, but the best results come from home treatment several times a day.

With the small, weak bulb of the pipette, while the patient can get all permissible exercise of the membrane, he can do himself no harm. This is not the case even when his lips take the place of the bulb. He should be cautioned not to overdo the Valsalva or Politzer inflation, which ought always to precede the exercise and be repeated frequently during its continuance. The stronger suction and compression for breaking up adhesions, etc., whether made with the mouth or with a large bulb or syringe, must be employed only under sight through the Siegle speculum, and then only by the expert otologist.

John Winslow, M.D.

Ithaca, N. Y.

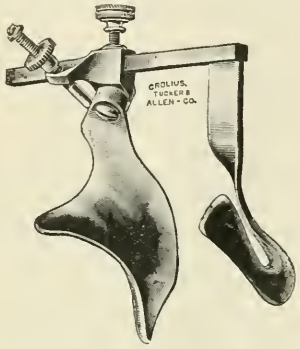
Intratympanic Surgery.—The results of excision of the necrotic ossicles in chronic purulent otitis media may be summed up as: 1. Prompt lessening of the discharge in all cases. 2. Ultimate cessation of the discharge and cicatrization of the fundus in nearly one-half of the cases, as observed so far. 3. Arrest of the advance of caries and necrosis in the drum cavity, aditus, antrum, and mastoid cells, thus lessening the liability of the occurrence of intracranial lesions of otitic origin. 4. Improvement in hearing in more than half the cases. 5. Marked amelioration in the general health, especially in those cases presenting symptoms of slight septicæmia from the chronic purulency.—Dr. Charles H. Burnett, *International Medical Magazine*, December, 1897.

New Instruments.

NEW SELF-RETAINING VAGINAL SPECULUM.

By A. W. ABBOTT, M.D.,
MINNEAPOLIS, MINN.

This speculum is self-retaining and is equally useful in all positions. It should be introduced closed, the large blade toward the posterior vaginal wall. The



forefinger is then introduced between the blades, and by making counterpressure with the thumb on the bar the requisite divergence is obtained and then fixed by means of the nut on the retaining-screw. The blades are then spread to the required length by sliding the posterior blade on the bar. To remove the speculum, simply reverse the process. With this instrument and without assistants, curettage, trachelorrhaphy, vesico-vaginal operations, and uterine and vaginal dressings have been made. This instrument was made for me by the Crolius, Tucker & Allen Company, of Minneapolis, Minn.

A DEVICE FOR TURNING OFF THE CAROTIDS IN OPERATIONS ON THE HEAD AND NECK.[1]

By ROBERT W. JOHNSON, M.D.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BALTIMORE MEDICAL COLLEGE, BALTIMORE, MD.

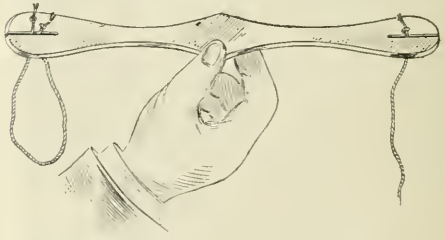
It goes without saying that the loss of blood in the vast majority of surgical cases is a serious item, and contributes largely to the bad outcome of operations—first, because the shock consequent to operations is often proportionate to the amount of blood lost, so that we see our careful surgeon's wounds bristling with hæmostats and new inventions like Esmarch's bandage hailed with delight and immediate adoption; secondly, because the flow of blood impedes the work of the surgeon, necessitating sponging and delay and often obscuring the field in the vicinity of important tissues, when an accurate knowledge of the exact relations must be kept in sight as well as mapped out by the anatomical acumen of the educated index finger.

It is, however, when we come to operate above the clavicle—speaking broadly, in the vicinity of the air passages—that a new danger is added to blood loss, one that is partly mechanical, partly biological, and that is the entrance of blood into the lung or trachea—mechanical, in that in large quantities it may drown the patient; biological, in that pneumonia or sepsis often follows in its wake. Various methods of obviating these dangers have been practised. Trendelenburg's position, with the head down, has the advantage of gravity, but allowing the blood to flow away from the trachea does not stop it, nor does it do away with the suction force of the lung, which may, in spite of the position, suck blood back into the larynx. Pressure on the carotids is a clumsy attempt at checking hemorrhage, inasmuch as the thumb or finger presses on the pneumogastric or possibly on the phrenic; and even if that objection were obviated, it is unreliable. Esmarch's bandage applied over the carotids but under the larynx is an example of science gone to seed. Once it bore Dead Sea fruit in a death on the table, probably from the pressure on nerve or venous trunks.

The écraseur and cautery are more or less dumb witnesses that blood must be stopped, even if we have to crush or cook the part to accomplish our end, temporarily at best, with anxious moments to follow the sloughing, lest secondary hemorrhage supplement the destruction that primary failed to produce. Chemical hæmostats—especially that abomination (in most instances), Monsel's solution—are rather medical than surgical, and, if applicable, are only for capillary rather than for arterial or venous bleeding. The same may be said of gauze packing, though in itself a most valuable hæmostat for postoperative oozing.

Ligation remains as reliable, and in the main it is satisfactory, if only we could avoid the loss of blood from tissues that do not require a ligature provided they have a little time for clot building.

What Esmarch's bandage has done for the extremities I trust this little device may accomplish in a small degree for areas supplied by the carotids. I had hoped to extend its usefulness to operations on the brain, but recent experiments on dogs have shown me that not only will they live with both carotids tied simultaneously and permanently, but the cerebral hemorrhage is scarcely affected, so great is the intercommunication with the vertebral arteries, and that they bleed profusely from brain incisions with both carotids ligated. In order to give some idea of the ease with which the common carotid may be exposed at the point of election, let me quote Nélaton, who said: "It takes four minutes for a man to bleed to death from the carotid, while two minutes are sufficient to tie it" ("American Text-Book of Surgery," page 639). "In uncomplicated cases the operation is very simple" (Treves, vol. i., page 154). It is unnecessary to multiply testimony as to its feasibility, especially if you have had experience in exposing it yourselves; few operations are easier. Rivington and Treves



called attention to the value of holding up the carotid as a hæmostat (*The Lancet*, January 21, 1888, page 111). The object of this paper is to show that either carotid may be held up alternately without injuring the brain structure, and that both may be held up for a short space of time or intermittently for a longer time, without permanent injury to the patient. This is accomplished by the very simple device here shown.

A silk ligature, of sufficient thickness (say, No. 14) to avoid cutting or bruising the artery, is passed around the common carotid on one or both sides of the neck, preferably at the point of election just above the omohyoid, care being taken to avoid the pneumogastric and to open the sheath only far enough to pass

[1] Read before the Clinical Society of Maryland, February 18, 1898.

the aneurism needle with a suture around the carotid. The external wounds may now be closed by suture or we may allow a short interval between the sutures for the play of the ligature. It is better to close the wound before beginning the main operation, as there is less liability to infection.

The knotted ends of the ligature are caught in the split at the end of the soft-wood bobbin, and when the arteries are so secured the assistant, raising or depressing one or other end of the bobbin, controls the artery on which the temporary tension is put. Thus in operating on vascular growths of the posterior nares or pharynx involving the median line, he can follow the operator with his eye, and, as the latter veers to one or the other side, can raise the corresponding carotid and cut off the circulation; or for brief intervals he can raise both ends and thus close both carotids, until the arteries exposed by the operator in the main operation can be secured.

From experiments on dogs as well as from the history of cases when both carotids have been tied, I feel that we run but little risk in temporarily cutting off the brain from that blood supply, especially as we can restore it readily by loosening the vessels, should unpleasant symptoms arise. When the operation is over, or rather when bloodshed is over, one end of each loop should be cut close to the skin and the rest of it drawn through the wound from behind the artery, thus diminishing the chance of infection and in no way destroying the sutures or dressings.

Operations involving areas outside of the brain itself which are supplied by the carotids may thus be rendered almost bloodless by a procedure nearly as simple under asepsis as turning off spigots in a bath-room.

A PORTABLE OPERATING-ROOM FOR FIELD SERVICE.

By L. E. COFER, M.D.,
U. S. MARINE HOSPITAL SERVICE, SAN DIEGO, CAL.

The portable operating-room, sketches of which are shown herewith, is intended for use during engagements or skirmishes by either military or naval landing forces. It may be drawn by members of the hospital corps or dragged behind an ambulance. During an engagement, after it has been drawn to a protected spot, the four operating-tables may be quickly unfolded and the awnings spread, there affording, it is believed, the maximum amount of surgical emergency equipment in the most convenient form. Not only is it possible with this device to operate on or treat four patients at once, but if necessary they may be left on the tables, thereby turning the operating-room into an improvised hospital tent. Not being a mechanic, I must leave the details and possible difficulties attendant upon its successful construction to the instrument maker. I would suggest, however, that the material be white enamelled iron or steel frames. Wheels of the kind used on bicycles would be a great advantage, as they combine lightness and strength. A description of its various parts is given under Figs. 1 and 2.

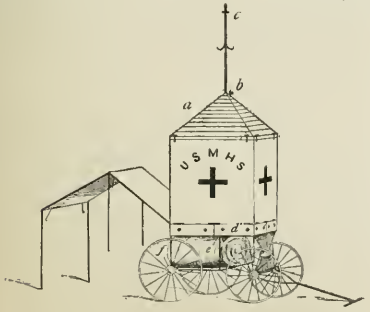


Fig. 1.—Showing Portable Operating-Room Ready for Transportation, also Method of Folding Table. *a*, Tank for sterilized water or decinormal salt solution; *b*, tap for filling tank; *c*, rod for centre hole of tent; *d*, zinc-lined drawers for storage of instruments and for use as instrument trays; *e*, folded tent in cage (*f*); the latter should also hold extension tent rods and guy ropes.

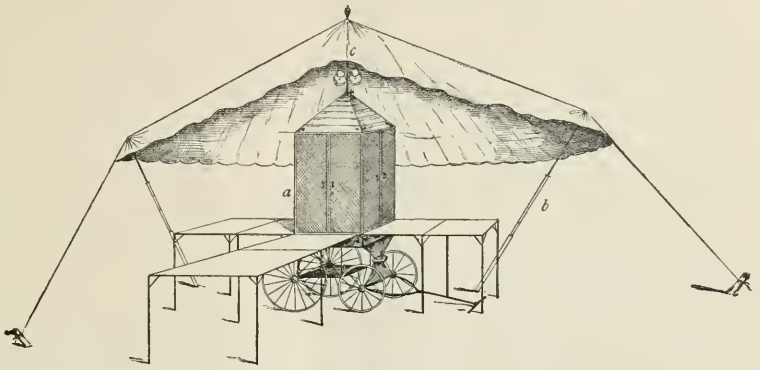

Fig. 2.—Showing Portable Operating-Room Ready for Use. *a*, Wire cage divided into compartments to contain surgical emergency equipment; *b*, steel extension tent rods; *c*, lanterns.

Medical Items.

A Nervous Surgeon.—William Cheselden, the famous English surgeon who died in 1752, is related to have always been sick from anxiety before operating, and as the moment approached was pale from fear. But the instant he commenced his work all fear vanished, the hand was electrified with skill, and the operation was perfect.—*Asclepiad.*

Trepanning.—The custom of trepanning or taking a small piece of bone from the living head was much practised in prehistoric times, as the skulls prove to us, and is still in vogue among some peoples. Among these are the people of the Berber stock in the Djebal Amès and the Djebal Checkar of the edges of the Algerian plateau. The method of performing the operation is carefully described by Drs. H. Malbot and R. Verneau. Dr. Malbot was shown by a native doctor a skull with more than a dozen circular holes, two slits, and a large irregular orifice, all of which had been pierced when the man was alive. The skull was kept hidden, and was evidently used as an example by the local doctor. The natives have recourse to trepanning for blows or wounds on the head, and it does not matter how long before the blow may have been given, if only the sick person can remember that he has had one. The operation is not severe. A woman, tired of her husband, is said to have called in the service of a trepanner, in order to get a divorce from him by producing a piece of her skull and affirming that he had broken it in some of his cruel acts.

A Determined Suicide.—A man was arrested for poaching on fish preserves by means of dynamite cartridges. He decided to take his own life by the same means. He placed the cartridge under his chin, but, the effect of dynamite explosions being most marked downward, the chief effect was to damage the hand which held the cartridge and the other hand to a less extent. He then lay down on the ground, placed a cartridge on his chest, and with great difficulty, owing to the injury to his hands, struck a match after many attempts, and applied it to the fuse. The thorax and abdomen were completely emptied of their contents, and the corresponding parts of the vertebral column and ribs were also missing. The other parts of the body were not injured.—*Medical Press and Circular.*

John Hunter Angry.—Mr. Paget, in his "Life of Hunter," says that the great surgeon was only once, so far as is known, rough and brutal to his patients or their friends; he asked leave to make a post-mortem examination and it was refused. Over this loss of precious knowledge he forgot himself. Abernethy tells the story as he heard it from an eye witness: When he was conscious that his object was unattainable, he was standing with his back to the fire and he put his hands into his pockets. He gravely and calmly addressed the master of the house in the following manner: "Then, sir, you will not permit the examination to be made?" "It is impossible," was the reply. "Then, sir," said Mr. Hunter, "I heartily hope that yourself and all your family, nay, all your friends, may die of that same disease, and that no one may be able to afford any assistance."

The Parisian Doctor's Black List.—According to an English weekly journal, when a Parisian doctor is called upon to attend a new patient, even though the case be a most urgent one, he first consults a book, fittingly bound in black, and if he finds the sick person's name recorded there he declines to go. For in this "black book" is a list of the names of those who have received medical services but who, though pecuniarily able, have refused to pay their doctor's bill. The book is issued by the great medical society of Paris, whose members have agreed to observe the rules which came into effect some short time ago. These rules provide that each physician shall keep a careful record, which he shall forward to the officers of the society at stated intervals, of the names of those whom he has attended who have refused to pay him his fee. Every reasonable effort should first be made, however, to collect the bill, and only when the patient's debt has been paid will his name be erased from the list. This doctor's black list is the result of the superabundance of doctors, many of whom find it hard to make more than a bare living, and suffer much annoyance from uncollectable debts.

Stimulants.—The first choice of any particular stimulant seems to depend on such altogether accidental circumstances as the accessibility or cheapness of this or that special medium of intoxication. Orchard countries use distilled or vinous tipples; grain lands waste their products on malt liquors. The pastoral Turkomans fuddle with kumyss, or fermented mare's milk, the Ashantees with sorgho beer, the Mexicans with pulque (aloe sap), the Chinese and Persians with opium and hasheesh (cannabis indica), the Peruvians with the acrid leaves of the coca tree. Even mineral poisons have their votaries. There are thousands of arsenic eaters in the southern Alps. Arsenious acid, antimony, cinnabar, and acetate of copper are mistaken for digestive tonics by Spanish and South American miners. By the process of fermentation rice, sago, honey, sugar, durrha (Sorghum vulgaris), dates, plums, currants, and innumerable other berries and fruits have been converted into stimulants. The Indians on the Llanos Ventosos in the Mexican State of Oaxaca stupefy themselves with macerated cicuta, a kind of water hemlock, and it is said that the delirium and subsequent reaction of a cicuta debauch correspond exactly to the successive phases of a whiskey spree, the only difference being in the price of the tipple. If intoxication were a physiological necessity, it would, indeed, be folly to buy the stimulant at the dramshops, since cheaper poisons would serve the same purpose. A dime's worth of arsenic would protract the stimulant fever for a week, with all the alternate excitements and dejections of an alcohol revel. A man might get used to phosphorus and inflame his liver with the same lucifer matches he uses to light his lamp; we might gather jimson weed or aconite or fuddle with mushrooms, like the natives of Kamchatka, who prepare a highly intoxicating liquor from a decoction of the common fly toadstool (Agaricus maculatus).—Oswald, *in The Popular Science Monthly.*

English and Metric Weights and Measures.—The following comparative summary of English and metric standards of measurement of weights and measures may be useful: The English inch is equivalent to 2.54 centimetres; the foot to 30.48 centimetres; the yard to 94.44 centimetres; the mile to 1,609.33 metres; the nautical mile to 1,852.30 metres. The square inch is equivalent to 16.387 cubic centimetres; the cubic foot to 28.516 cubic decimetres; the cubic yard to 764.535 cubic decimetres; the pint to 0.567 cubic decimetre; the gallon to 45.410 cubic decimetres. The English grain is equivalent to 64.799 milligrams; the ounce avoirdupois to 28.349 grams; the pound to 453.590 grams; the ton to 1,016.050 kilograms. The foot pound is equivalent to 0.13825 kilogrammetre; the French horse power to 75 kilogrammetres a second; and the English horse power (550 foot pounds a second or 33,000 foot pounds a minute) to 76 kilogrammetres a second. The metrical unit of pressure is the kilogram per square centimetre. We may also count by centimetres of mercury or by atmospheres. A pressure of one atmosphere corresponds to a column of mercury 76 centimetres high, or to 1.033 kilograms per square centimetre. The English pound per square inch corresponds with 70.3 grams per square centimetre.

Quain the Host vs. Quain the Doctor.—Many good stories are told of Sir Richard Quain, whose social distinction had latterly overshadowed his medical reputation. One of the most characteristic of them was that of the friend patient who was first urgently warned by Sir Richard Quain, the physician, against touching champagne or port, and shortly afterward equally warmly urged by Sir Richard, the host, to try very special brands of those wines, which he had brought out for his guest. The guest patient laughed and drank, and pondered on the mysteries of medical advice.

Hair.—A writer in an English weekly journal says that it is a curious fact that red-haired people are far less apt to go bald than those with other colored hair. The average crop on the head of a red-haired person is only 29,200 hairs. Ordinary dark hair is far finer, and over three dark hairs take up the space of one red one; 105,000 are about the average. But fair-haired people are still better off; 140,000 to 160,000 are quite a common number of hairs on the scalp of a fair-haired man or woman. A curious calculation has been made, to the effect that the hairs on the head of a fair-haired person, if they could be plaited together, would sustain a weight of something like eighty tons, equalling that of five hundred people.

FRACTURES OF THE BONES OF THE FACE.[1]

By C. C. WARDEN, M.D.,
NASHVILLE, TENN.

In studying fractures of the bones of the face there must of necessity arise some slight difficulty in classification, since injuries in this region commonly involve portions of the bones of the cranium, such as the frontal and ethmoid, without inflicting damage to such facial bones as the palate and lacrymal. I shall endeavor, however, to confine this paper to the limits of its title, fractures in other regions as possible complications.

Reports from the London and Berlin hospitals[2] show that out of 1,876 fractures of the bones of the face there were 453 of the inferior maxilla, 268 of the nose, and 142 of the superior maxilla and zygoma. We may consequently safely infer that the inferior maxilla is fractured four times more frequently than the superior maxilla, and twice as frequently as the nose.

The subject may be divided, then, for separate consideration into fractures of the inferior maxilla, nasal, superior maxilla, malar, palatal, inferior turbinated, and lacrymal bones in the order named.

Fractures of the Inferior Maxilla.—These injuries are most common during the second and third decades of life. They occur eleven times more frequently in males than in females and are rare during infancy, childhood, and old age.

The factors causing the comparative immunity of youth and age are obvious and directly due to difference in exposure and occupation at such periods of life. Rickets as an etiological factor in children should not be forgotten, though there is much doubt if this disease materially increases the percentage of fractures of this bone. The changes occurring in the inferior maxilla in old age, which are a reduction in size due to absorption and alteration in form, doubtless render the bone more liable to fracture than at other periods of existence, and such instances would be numerous were it not for the safeguards which sedentary persuits of age afford. Climate may be dismissed as of practically no causal importance. The intense cold of the Lake Superior region has not to my observation ever materially increased the number of cases. Broken bones are extremely common, to be sure, but directly due to the hazardous occupations of timbering and mining, and the precarious pastimes of snowshoeing, tobogganing, and skiing. The immediate cause of fracture is always direct violence applied to the parts. The statement that violent contraction of the temporal muscles will snap off the tip of the coronoid process need hardly be considered, since there is nothing to substantiate it. Blows upon the chin or any portion of the jaw, falls upon the face, the impetus of some flying object, sudden turning of the head to encounter resistance, faulty attempts or hasty and careless efforts to open the jaws during narcosis, and incautious extraction of teeth, are all immediate causes.

The line of fracture may occur at any portion of the body and rami, or rarely through the processes of the bone.

Fractures of the condyles are rare and depend principally upon blows or falls upon the chin. The coronoid processes are seldom alone involved, but usually at the same time there is extensive damage to the malar and zygoma. Probably the most frequent site of breaking is through the body on either side of the symphysis, anterior to the last molar tooth. Fractures through the symphysis are also common.

The line of fracture is generally transverse in these localities, with or without splintering, according to the quality of the shattering force. Behind the last molar tooth the line of separation generally extends downward and backward, and this direction is usually met with in fractures through the angle. Fractures may be simple, double, or multiple, comminuted or compound. The double variety is quite common, owing to the fracturing force being frequently applied to the side of the face, and usually the lines of breakage are nearly opposite—that is to say, symmetrical. Such double fractures are particularly liable to be compound, owing to the frequency with which the gums are lacerated by the lateral dislocation.

Deformity is common. The fragments may be vertically displaced, as shown by the difference in level of the teeth, or they may override. In double fractures the anterior fragment is usually lower than its fellow, and held to one side by the action of the breaking force and possibly by the action of the muscles. Deformity following single fractures is liable to be due to some slight obliquity in the line of fracture rather than to muscular action. This condition is particularly apt to occur when the break is lateral somewhere between the incisor and the last molar teeth. Fractures in the angle do not yield much if any deformity, owing to the steadying action of the masseter and pterygoid muscles.

Condyloid fractures show usually no deformity at all, unless the internal pterygoid carries the condyle forward, when the jaw becomes slightly tilted toward the wounded side.

The symptoms are pain, abnormal mobility, swelling, deformity, and crepitation. The injuries that occur anterior to the angle of the jaw are always clearly demonstrable—as is the case too with fractures through the ramus—by palpation, both within and without the mouth, in conjunction with the usual symptoms and physical signs. The most difficulty will be encountered in diagnosing lesions in the superior portion of the ramus, at the neck, and through the condyle, for the reason that these points are less accessible and well protected. There should be no difficulty, however, in fully satisfying one's self of the nature of the injury, since anæsthesia in these cases gives us the needed assistance.

The treatment consists in accurate correction of the deformity and rest by immobilization of the affected parts. Nearly all fractures unite kindly and quickly, or at least have a marked tendency to do so unless hampered with detached, suppurating, necrosed frag-

[1] Read before the Nashville Academy of Medicine, January 14, 1898.

ments or splinters. Four weeks at the utmost should bring about good bony union and fair restoration of function. There are many agents at our disposal for the maintenance of correct position. Numerous splints, both external and moulded interdental, have been devised. It may be safely said that nature's own splint, the upper jaw and teeth, affords the simplest, safest, and best splint for the affected parts. When the teeth are in good preservation the fracture should be accurately reduced by careful manipulation, and the lower jaw brought up against the upper in a position natural and comfortable to the patient and secured there. The patient's subjective sense is very helpful. He usually will assert whether or not his teeth fit together in the proper manner. A moulded pasteboard, yucca, gutta percha, or fret splint should be applied to the outer surface of the jaw and contiguous portions of the neck, and retained in place by firm bandaging. Feeding can in nearly every case be conveniently effected through the posterior dental space. I would suggest that the term spoon victuals, rather than slops, which Mr. Waltham makes use of, be employed as a slightly more elegant term, to designate the particular consistence of nourishment required. Wiring the teeth nearest the line of fracture is a common procedure, but is often inapplicable, since the teeth are commonly loosened at the time of the injury, and, if not, will speedily become so when securely wired. A better plan is to include all the teeth with a stout wire running in a groove in a moulded vulcanized-rubber or gutta-percha shield, which fits the outer surface of the teeth and gums. The end of the wire may be anchored securely around the last molar teeth, and twisted together in front at the median line. By this means there is no dragging on any particular teeth. Interdental splints are often very serviceable when accurately applied by a competent dentist, and at times are alone applicable, owing to wide irregularities in the teeth. They also permit of motion of the jaw, which may be in certain cases advisable. When it is difficult to correct deformity or to maintain a proper position, on account of small comminuted fragments or splinters of bone, it will be entirely permissible to cut down upon the fracture within or without the mouth, and by trimming or removing fragments to bring the parts into close apposition. We do not thereby greatly diminish the speediness of recovery, but by so doing are able to lessen the remote chances of delayed union and pseudarthrosis and to prevent abscesses, which are liable to form under such conditions. This practice is of course facilitated when the fracture is already compound.

The toilet of the mouth should be attended to with care and the cavity should be cleansed several times daily with non-irritating antiseptic washes.

Fracture of the Nasal Bones is always the result of direct violence. One or both bones may be broken. Such injuries are most common in males during the third decade of life, and are quite rare in females and children, particularly among the upper classes. The present athletic tendency of females has to some extent brought up their average—how much it would be interesting to know—and bicycle riding appears to be a fruitful source of such injury. The fracture may be simple, comminuted, or compound. The lines of fracture may be transverse, oblique, or longitudinal, more often the first variety. Simple single fractures without deformity are not so rare as supposed, and careful investigation of the injuries in this region would frequently demonstrate their existence. Usually the fracture is double or multiple and the deformity quite apparent. The lower fragments are usually depressed, sometimes to the level of the nasal process of the superior maxilla, and frequently there exists considerable inward or lateral displacement.

Deformity as a result is marked. The most noticeable and serious deformity occurs when the nose is broken by a blow upon the bridge, applied directly from before backward, causing a depression and flattening.

It must not be forgotten that fractures in this region are frequently complicated by injuries to contiguous bony structures, such as the spine of the frontal bone, the cribriform and vertical plates of the ethmoid, and the nasal processes of the superior maxillæ. Again, there may be a disarticulation of the triangular cartilage, and very rarely and only in extensive smashes of the face we may meet with fractures or disarticulation of the inferior turbinated bodies. The perpendicular plate of the ethmoid usually yields sooner than transmit breaking-force to the cribriform plate, yet this plate may be involved in fractures high up toward the frontal ridge. The possibilities of this complication should be well borne in mind.

The symptoms of fracture of the nasal bones are hemorrhage, swelling, deformity, and crepitation. The patient will complain of intense pain, particularly on manipulation of the affected parts. Hemorrhage may be profuse but not necessarily dangerous or exhausting. Coexistent with the swelling may be noticed emphysema of the eyelids and face and a general puffy condition of the whole midfacial triangle. Crepitation is usually easy of demonstration and is quite characteristic in multiple fractures, yielding a sensation as if the fingers were kneading thin parchment. The deformity may be partially or entirely masked by the swollen tissues, particularly after the injury is a few hours old.

The tendency to repair is active. A week will suffice to bring about such firm union that attempted repair of recurring deformity may be wellnigh impossible.

The treatment consists in reducing as accurately as possible such deformity as exists, and affording support and rest to the part by maintaining the fragments in correct position and guarding them from further injury. The turgid mucous membranes may cause the patient great annoyance, and will prove a fruitful source of relapsing malposition, because of the respiratory efforts to gain a free passage for air. The patient should be cautioned against such efforts.

Reduction of these fractures when there exists considerable fragmentation is always difficult. The bones should be moulded into position by the fingers of the operator from without, aided by the counter-pressure from within of a stiff, stout probe or director. And here the question of anæsthesia will arise, since the patient almost invariably refuses to submit to this treatment. The director or probe in use should be blunt pointed, and the instrument should not be carried too high, since there may exist some doubt as to the integrity of the cribriform plate. Should there be a tendency to slip on the part of the fragments, the difficulty may be overcome by anchoring them with a harelip pin or with metal braces, exerting steadying pressure from within. The practice of maintaining correct position by tamponing should be interdicted for humanity's sake. Sufficient pressure can be brought to bear upon the parts by using an ordinary hairpin properly bent and adjusted, the free end of which is embedded in a thin layer of cork, which is retained on the upper lip by rubber adhesive strips. A moulded thin felt splint applied so as to cover the entire bridge of the nose and portions of either cheek, retained in position by adhesive straps, will afford protection from without. Compound fractures offer serious difficulties and should receive all the surgeon's conscientious efforts to promote asepsis. It may often be necessary to render a badly comminuted fracture compound in order to maintain a correct position of fragments and

prevent subsequent suppuration. Such a proceeding is to be commended, since it is better surgery to cut preventively, it seems to me, than to be obliged to incise and drain abscesses later in the day. A small external cicatrix is infinitely more preferable than a permanent and unsightly deformity of the nose itself.

Fractures of the Superior Maxilla are nearly always limited to the processes of this bone, except when extremely violent and shattering force is applied. The nasal processes are commonly associated with the nasal bones in injuries and the malar processes with injuries of the malar bone and zygoma.

Fractures of the alveolar processes are common. The body of the bone is, however, broken at times and commonly involves with it the palate and pterygoid plates. We may confidently expect severe injury to soft structures and extensive damage, if not obliteration, of the antrum in such cases. Injuries to this bone are always due to direct violence, applied from without or from within through the mouth. The fracture may be simple, multiple, comminuted, or compound. The lines of fracture may extend in any direction, depending upon the character and direction of the force applied to cause them. The deformity is usually not extreme. In cases in which the whole bone is driven backward into the pharynx, the disfiguration is very apparent. Usually in cases of moderate damage some slight flattening of the face is observed, and oral examination will reveal the displacement, particularly when the alveolar or palatal processes are involved. There may exist considerable separation of the halves of the palate and usually there is a slight difference in level. The deformity is necessarily great in fractures of the nasal process associated with like injury to the nasal bone. Transverse fractures through the body above the alveolar processes are frequently met with and usually present no disfigurement whatever. Injuries to the orbital portion of the bone, including the ridge and the floor, are always accompanied by extravasation of blood into the orbit and cheeks, producing considerable bulging of the eyeball. Formications and anæsthesia frequently occur, because of damage to the second division of the fifth nerve. The symptoms are pain, swelling, deformity, and crepitation.

Fractures in this region present few difficulties in diagnosis. Single transverse fractures through the body of the bone may, however, pass undetected. Guerrin says that in this injury the pterygoid apophysis is invariably broken and pressure over its area will elicit pain. The exact amount of damage done in severe smashes of the superior maxilla cannot always be accurately determined, since the fracturing force may be continued or transmitted to the bones of the base of the skull. It is not the province of this paper to discuss fractures due to gunshot wounds through the mouth. It will suffice to say that nearly all such cases are of suicidal provocation and quite commonly fatal. Fractures near the inner canthus, particularly when compound, are liable to cause damage to the nasal duct or even its obliteration.

The treatment of these injuries demands restoration of normal relations as near as possible. The fractured nasal processes should be subjected to moulding and adjustment just as the fractured nasal bone. The same apparatus, slightly modified to suit the case, may be employed. Severe comminution of these processes is apt to be followed by necrosis of fragments. The bone here is very thin and fragile, and when detached completely or badly fragmented quickly suppurates and is sloughed off. Injury to the lower turbinated bodies may require their partial removal, particularly if the fracture be compounded within the nose. The septum, if broken or bent out of proper alignment, should be straightened. In cases in which the damage to the body and orbital portions is extensive and there is much pulverization of the bony parts, it may be well to render the injury compound, if it be not already so, either from within or from without, and remove the detached fragments, since by so doing the patient may be spared the long-continued and offensive suppuration that is otherwise almost inevitable. Simple fractures through the body rarely require further treatment than protection and rest. When separation occurs between the palatal processes, it will be found that if the parts can be maintained at the same level the gap will close of itself, as a general rule, without deformity. When fractures involve the alveolar processes the fragments should be replaced and maintained in position by wiring the teeth or by the aid of interdental splints. No effort should be made to remove loose teeth, but rather they should be pushed into position as nearly as possible, in the hope of saving them. In addition, the effort to extract the teeth might increase the damage already done. In spite of care these fragments are liable to separate and necrose. In such a contingency they should be removed.

Fractures of the Body or Processes of the Malar Bone occur as a result of violence applied to the face. The commonest injuries to this bone are those in which the body is broken and driven inward together with the malar process of the superior maxilla, with consequent damage to the antrum. More rarely there may exist a simple fracture, the line running more or less vertical or transverse.

Gurlt insists that a simple diastasis may occur, and claims to have recorded a few instances. This injury is of all most rare. It practically cannot be produced on the cadaver, though the lines of fracture may closely follow the direction of the sutures. Fractures of the zygomatic process, together with the corresponding shaft of the temporal, are of more common occurrence, and may be complicated by fracture of the coronoid process of the inferior maxilla. The varieties of fracture are simple, compound, or comminuted. Of these, compound injuries are rarest.

The symptoms are pain, swelling, deformity, and crepitation. Pain is particularly acute in this region, and rarely will the patient submit to manipulation of the parts. The diagnosis is largely dependent on deformity and crepitation, particularly the latter, since a simple fracture deformity is liable to be wholly wanting. When the line of fracture traverses the portion of bone forming the outer wall of the orbit, the eye may bulge from the pressure of extravasated blood. There will also be considerable effusion into the surrounding tissues. Severe crushing-injuries with inward displacement of fragments and obliteration of the maxillary sinus are not difficult of recognition, owing to the characteristic sunken appearance of the cheek and the sensation of distinct crepitus that is always elicited.

The treatment consists in coaptation of fragments and protection to the part. Moulding of the shattered parts is frequently most difficult, since there is little opportunity to elevate fragments unless the fracture be compounded. The finger passed up within the mouth along the cheek will be able to render considerable assistance. If a hook can be brought beneath the depressed portions and carried forward, the aim may be accomplished.

The necessity of cutting down upon the bone for this purpose may meet the surgeon. Depressed fractures of the zygomatic arch are more easily remedied because of the fossæ above and below. Splints are valuable, in so far as they afford protection to the injured part. Union takes place rapidly, hence the necessity for early attempts at reduction. There is not excessive formation of callus.

Extensive injuries to the face may include fractures of the hard palate. The orbital plate of the palate is

rarely ever broken unless there is serious damage to the floor of the orbit. It is difficult to conceive of this process being shattered, but it may be dislocated from its position and dragged downward or wedged upward by a fracture occurring in the vertical plate, produced by a force applied toward the median line. In such instances the sight is imperilled, because of commonly resulting opacity of the vitreous humor, if for no actual evisceration of the eye. The vertical portion of the bone may be fractured by a violent blow, which at the same time shatters the body of the superior maxilla covering it. The horizontal plate may become broken by any force that will produce injuries to the palatal processes of the superior maxilla, such as smashes of the face, gunshot wounds, or falls upon pipes or sticks held in the mouth. The position of the bone, forming as it does the lateral wall and part of the floor of the nasal cavity, necessarily limits to the nasal passage the deformity following fracture. The damage inflicted may be excessive and result in considerable narrowing of the canal, or in cases of necrosis, in actual enlargement. Any bending of the bone inward drives the turbinated bodies against the septum. The middle and inferior turbinated bodies generally share the fracture. Deformity resulting from fracture of the horizontal plate in the lower half of the vertical portion may be demonstrated by intranasal examination. Fractures and their deformities above the middle half and including the orbital plate are extremely difficult of demonstration unless the injury be compound. In this case the finger or examining instrument may be made to impinge upon the floor of the orbit. The lines of fracture are variable.

The symptoms are those accompanying fracture elsewhere.

The diagnosis depends upon the ability of the surgeon to demonstrate deformity or crepitation.

The treatment should be similar to that accorded severe fractures of the superior maxilla. Restoration of normal relations is exceedingly difficult. The fragments of the bone are so fragile that they show a decided tendency to necrose and disappear by diapyesis. It is well in compound fractures to remove those pieces entirely detached and forestall the suppuration. Apparatus for bracing the floor and lateral wall may be employed to maintain reduction, yet in cases in which deformity is slight the fragments have a tendency to remain in position when placed there. This is true particularly of any subsequent inward displacement. In extensive fragmentation of this bone and superior maxilla I would recommend the removal of all detached fragments possible, particularly when a compound fracture exists. Should the overlying soft parts be lacerated, it will be well to incise further, if necessary, to facilitate the operation. Drainage once established through the nose and mouth will insure subsequent speedy and kind healing of the external wound. Whatever linear cicatrices result would seem preferable to the foul and tedious suppuration to which without this interference the patient is surely doomed.

Fracture of the inferior turbinated bodies may be dismissed with a word or two. The possibility of injuries to these bones has been mentioned above. They are rarely damaged singly.

The Lacrymal Bones are very rarely subjected to fracture, owing to their protected position. If the articulation of these bones be recalled, it will become evident that the liability to damage depends materially on force transmitted through the superior maxilla and the frontal. It may be said that injuries are never inflicted from association with the inferior turbinated or the os planum of the ethmoid.

In no wise are subjects better illustrated than by presentation of cases bearing upon them. I am so fortunate as to have notes bearing on cases which embrace fractures of nearly all the facial bones.

Case I.—Joseph G——, Cornish boy, aged twelve years. An active youth and an iron miner by occupation. The case was first seen by me in December, 1896, in consultation with Dr. G. G. Barnett, of Ishpeming. The boy was underground, standing near a tramway. A car loaded with timber was passing and one of the projecting beams struck him on the right side of the face, causing a double symmetrical compound fracture of the inferior maxilla with a decided dislocation of the anterior fragment to the left. Hemorrhage was profuse. Examination showed downward and nearly transverse double lines of fracture in front of the last molar tooth, compounded within the mouth on each side. The deformity was corrected by digital manipulation of the parts, when the hemorrhage ceased. It became evident that the lines of fracture were slightly bevelled alike on either side, causing a tendency to left lateral recurring displacement of the forward fragment. The teeth were not markedly loosened. No attempt was made at wiring them, because it was thought that proper external splints to retain correctly the jaw against its fellow would meet all the requirements of the case.

Accordingly the jaw was carried up against the upper and placed in a well-fitting position, the patient assisting by testifying that his teeth felt right. A well-padded splint of thick cardboard, moulded by notching where necessary, was applied and firmly secured by free bandaging. The patient was fed through the postdental space. Subsequent suppuration demonstrated the existence of splinters that had escaped detection. The toilet of the mouth was well cared for. The boy made a good recovery without the formation of excessive callus, in spite of the fact that his chief amusement consisted in endeavoring constantly to loosen the dressings by efforts to move the jaw as much as possible, without giving himself unnecessary pain. Six months after the injury the jaw was strong and well, and to the eye presented no deformity. Digital examination revealed a slight projection of the right inner edge of the anterior fragment and a corresponding projection of the left inner edge of the posterior fragment on the other side. The rotation was slight, however, and proper approximation of the teeth and jaws was not interfered with.

Case II.—In June, 1896, John W——, an English boy, aged eleven years, was driving with his father in a light road wagon. The horse became frightened and ran, dragging the wagon and occupants over an abandoned portion of sunken road which had been filled with large rocks. The father was thrown out. The boy was thrown from the seat into the bottom of the wagon in such a way that his face was repeatedly jammed with great violence against the iron foot rail. The patient was brought to the hospital and anæsthetized. After the face had been cleaned the following appearance was presented: The entire left half of the face was swollen and ecchymotic, the eyeball protruded markedly, and the pupil was widely dilated. Beginning at the mouth and extending vertically upward to the left ala of the nose was a complete laceration of the soft parts. Palpation showed that the left half of the superior maxilla and the nasal process thereof, the left malar, and both nasal bones were badly comminuted. Separation of the lips of the laceration revealed the apex of an angle of depressed fracture of the body of the superior maxilla. This angle, one-half an inch in width at the apex and beginning at a point three-quarters of an inch above the alveolar border over the left second bicuspid tooth, continued upward with rapid diverging sides so as to include the left nasal process, inferior turbinated, vertical portion of the palate, both nasal bones, left malar, and zygoma.

The finger introduced into this enormous cavity impinged against broken detached fragments and pulpified tissue. The finger carried upward to the orbit was able to detect fracture in the floor of the orbit. The lacrymal and superior maxillary and ethmoidal portions were broken and driven slightly upward and inward, so as to present a flattened instead of a convex outline to the finger. The maxillary sinus was completely obliterated. No damage was done to the alveolar border. Damage to the cribriform plate was suspected, as all portions of the nasal bones high up were shattered. There was no marked deformity of the nose or face at the time, because of the swelling. Hemorrhage was not severe.

An incision was made through the skin and tissues, beginning at a point below the inner canthus of the left eye and carried down along the border of the nose, to terminate in the summit of the laceration. The skin was reflected and all entirely detached fragments were removed, some twenty in number. Those that seemed thoroughly adherent were allowed to remain in position, in the hope that they would retain their vitality. The nasal bones and the left nasal process of the superior maxilla were straightened by external moulding, aided by the internal counterpressure of a director and a finger within the cavity. Nothing was done to correct the orbital displacement. The laceration and incision in the soft parts were sutured, and drainage was established through the nostril, nares, and mouth, under the upper lip. Gauze strips packed through either of these openings met in the large general cavity. The malar and zygoma, though fractured, were not displaced, so they were not molested. The subsequent aspect of the case showed conclusively that all fragments should have been removed in this instance. For weeks there was constant and offensive discharge backward through the nares and externally through the nostril and beneath the lip. Some fragments of the right nasal bone necrosed and formed an abscess which pointed externally. This was accordingly incised and drained. The incision and laceration healed kindly by first intention. The wound was dressed daily for more than thirty days. The discharge gradually diminished and the enormous cavity slowly filled. The left eye receded to almost its normal position. Its motions were not impaired. The pupil remained dilated and irresponsive to light. The sight of the eye was irrevocably lost. Dr. Andrus, of Ishpeming, kindly made an ophthalmoscopic examination of the eye soon after the injury, and reported that a dense opacity of the vitreous completely masked the fundus. One year after the accident the boy presented the following appearance: The nose was of natural vertical contour. The left aspect of the face, including the left side of the nose and the portion of the cheek lying below the orbit, was slightly flattened and depressed. The malar prominence showed a slight dipping off toward the depression. The zygomatic area was like its opposite fellow. The left nasal passage was large and roomy and covered with healthy mucous membrane. The cicatrix of the incision and laceration was not noticeable, and indeed scarcely visible.

In earlier youth this boy had hip-joint disease, which left him a cripple and impaired his general health. The last misfortune does not, however, seem to have materially diminished his vigor.

133 North Spruce Street.

Epistaxis, when rebellious to other methods, may be arrested by making revulsion over the liver region by means of actual cautery, fluid vesicatories, tincture of iodine, or hot compresses.—August Latour, *Journal de Médecine*, January 10, 1898.

A REVIEW OF SOME OF THE CASES IN WHICH INSANE PERSONS HAVE BEEN RELEASED FROM CUSTODY BY THE COURTS WITHIN THE PAST SIX YEARS.

By CHARLES E. ATWOOD, B.S., M.D.,

CLINICAL ASSISTANT, NERVOUS DEPARTMENT, VANDERBILT CLINIC, NEW YORK; FIRST ASSISTANT PHYSICIAN, BLOOMINGDALE, WHITE PLAINS, N. Y.

Occasionally we see in the secular papers, perhaps with startling headlines, a long account of the liberation by the courts of "another sane person" from an asylum. The conservative physician reads these accounts with a smile and a grain of salt, perhaps congratulating himself that he was not one of the principals in the original commitment of the patient to the asylum, and often speculating as to the subsequent history of these patients after their liberation. It is to satisfy the physician's natural curiosity as to the future of patients discharged from custody by the courts rather than because of a feeling that justification is required by the custodians for so-called "illegal" detention of such patients, that I have written up the following cases, comprising all the male patients who have been discharged by the courts from the hospital with which I have been connected during the past six years.

In regard to so-called "illegal" detention of sane persons in hospitals for the insane in this State, a former member of the State commission in lunacy once remarked to me that in all of his experience he had never met with such a case. All the subjects of the following cases were properly committed and properly detained, and the result, even thus early, has clearly proved that they should not have been discharged. The triumphant acclamation of the court-room throng at the popular verdict of a jury of "not insane" has been followed in every case by unfortunate results that should have been avoided. The wide circulation which the newspapers gave to the trials of these cases has been supplemented in some of them by equally wide publication with startling headlines when the results have been direful; but usually the later history of these cases is not known. Some lessons may be learned from the later history; but, alas! the physician, who least needs the lessons, is the only one with whom we can with propriety discuss them, for we do not wish to make enemies or tread upon the mighty skirts of the law.

Case I.—Mr. W——, aged seventy-three years, case of senile dementia of four years' duration, was admitted March 22, 1893, and discharged April 18, 1893, on a writ of *habeas corpus*. A verbal return to the writ was made to the judge that the patient was still insane; that the writ was obtained by the persons who placed him in the hospital, who had the power to take him out without such proceedings, and that the institution would have made no objection to their doing so.

In answer to questions, the medical superintendent stated that Mr. W—— suffered from senile dementia in a mild form; that he was admitted in an exacerbation of his disease in which he was exalted in his ideas, over-confident in his abilities, confused in his recollections; had hallucinations of sight, was garrulous, becoming quickly incoherent in conversation; had amnesia, partial aphasia, and was in poor general health; that he had improved in many respects, but showed still some lack of memory of recent events, delusions of conspiracy, and general mental enfeeblement. The doctor further expressed as his opinion that the patient was not likely to injure himself or others, but should not burden himself with the cares of business, and that he might live outside safely if looked after by his friends. The patient was therefore discharged, and left the institution as improved.

This case simply illustrates a lack of knowledge on the part of the friends as to the *modus operandi* of removing a patient from a private hospital for the insane.

Case II.—The following case is a very different one: Mr. S——, Hebrew, merchant, aged forty-three years, single; was admitted in 1893, suffering from symptoms of general paresis in the first stage, these symptoms being entirely obvious to a physician, but of such a nature as to be unconvincing to a lay sheriff's jury, and the patient was discharged after a sensational contest in court.

The patient was committed in the usual way, on the sworn certificate of two physicians, duly approved by a judge of a court of record. His mother and one brother were insane, and there was a history of dissipation and worry as exciting causes. The brother of the patient stated that for a month he had been careless and forgetful in business contracts, and extravagant in his ideas of business management. He would order made in the factory several times the quantity of goods needed; would make contracts which his brothers would have to revoke; overdrew his bank account, and would seem to think that he had plenty of money in the bank, although told that such was not the case; and finally wished to marrry a woman of another faith, with whom he had been living for several years.

On admission the patient appreciated where he was and was able to talk coherently, but he presented nearly all of the somatic and psychic symptoms of general paresis in an early stage. There was general exaltation of the cœnæsthesis, as indicated especially by exhilaration of mind and a careless indifference to his present condition and future outlook. His pupils were myotic, knee jerks lively, tongue and muscles about the mouth slightly tremulous; he had slight hesitancy in speech, irritability, and grandiose ideas of his abilities. It was brought out in the testimony, and became a matter of public record, that the patient's entire business methods had undergone a change. From being a careful, conservative business man he had become careless, indifferent, and extravagant in his methods, and frequently involved the credit and standing of the firm by overdrawing his accounts, making extravagant purchases of unnecessary goods, etc. He also employed extra clerks and others connected with his business when the times were dull and the usual custom was to discharge some of those not required. In short, he acted as though he had millions at his command and unlimited power. On the day of his commitment he said: "I am the king, and the biggest man in the trade." He would sit or lie on a sofa abstractedly for hours at a time at his place of business, staring into vacancy and not speaking to any one, and when questioned about necessary matters showed great irritability and lack of appreciation of his duties as a member of the firm. He abstracted money from the envelopes containing the pay of the workgirls and drew checks on blank paper, paying the same without making a record of it in the check book. His chief *faux pas* were his engagement to be married to a young woman of a different religious faith and a purchase of $31,000 worth of goods at one time at an auction, such purchase being many times in excess of the usual and an exhibition of poor judgment on the part of the patient.

In court the patient conducted himself quietly until put upon the stand. As a witness he demeaned himself well in the direct examination, but in the cross-examination he showed great irritability and lack of self-control; was very abusive to the plaintiff's attorney and refused to answer many questions, even for the benefit of the jury and the commission, when those questions were addressed to him by the lawyer. He showed also by his replies that he had ideas of grandeur in reference to his abilities, and an apparent lack of appreciation of the impression his conduct might have on the jury, prejudicial to himself. At one time he feigned sleep, and claimed he did not hear the question propounded. His replies were childish and frequently made as if he thought them witty or smart, when they were often the reverse. When addressed by a juryman he made several replies. Altogether his conduct on the stand under cross-examination was prejudicial to him, and even occasioned *sotto-voce* remarks from outsiders within the writer's hearing that he must be insane.

The case dragged along through seven meetings of the court, and two days before the patient's release he made a homicidal attack in the hospital on an attendant with whom he was playing billiards. Four expert witnesses testified that the patient was suffering from general paresis in the first stage, and that he was incapable of managing himself or his estate. One expert witness of great repute examined him, with a view to testifying in his behalf; but, finding him suffering from paresis, declined to testify, so that no expert testimony was offered by the defence. In spite of these facts, the jury found a verdict that Mr. S—— was of sound mind. This verdict was a great surprise to medical men conversant with the case, but it met with great popular favor.

The newspapers reported that he was married to his *fiancée* the evening of the day of his discharge, and also that he expressed himself as intending to give his business his active personal attention.

The case was given the greatest notoriety, and it was thought that the jury and the mass of the people were firmly convinced that a sane Jew had been locked up in a lunatic asylum by his brother, to keep him from marrying a Christian.

The following quotation from *The Sun* relates briefly the sequel:

"A dissolution of partnership followed, and—— started a new concern. He was unsuccessful from the start and sunk his entire fortune in the venture. His wife clung to him through all of his troubles, and it was not long before she had to admit that his mind was affected. He was more childish than violent, however, and his wife would not hear of his being committed to an institution. About six weeks ago, however, he became so bad that she applied to Judge McAdam to have him sent to an asylum. He was taken to Middletown, where he failed rapidly and died on Friday."

The next case, Case III., is an illustration of gross ingratitude on the part of a senile dement, and serves rather as a lesson to ourselves than anything else.

Mr. K—— was admitted in 1893, suffering from symptoms of senile dementia. His age was sixty-nine years; he was single, born in Germany, moulder by occupation; of intemperate habits and a confirmed miser. He had led the life of a hermit for twenty years, having been during that time eccentric and peculiar, and a woman hater. Owing to his isolation in a hut on Gerard Avenue and his miserly and peculiar habits, he was frequently annoyed by boys and mischievous men; and it was for an act of violence on his part, in retaliation for these annoyances, that he was arrested and taken to Bellevue. A fellow employee, acting in the capacity of friend and knowing him to have considerable money secreted, obtained his commitment to a private hospital at a fair rate of compensation.

On admission, his person and clothing were found to be in an exceedingly filthy condition, and an entire new wardrobe was purchased for him by the hospital.

The patient was very filthy in his habits; his memory for recent events was poor; he was childish and he exhibited weakness of intellect except on the one

point of hoarding money. He said he had the monopoly in the manufacture of patterns and moulds for making confectionery, and acknowledged that he was worth about $35,000. He said he was arrested and taken to Bellevue to be killed.

He told me that he was born in a small village in Baden, Germany; that he never knew who his parents were; that he was brought up by a woman who treated him very cruelly; that he ran away from her at the age of seventeen to France; that his sweetheart followed him and lent him money; that he subsequently abandoned her and came to this country. Here he served in the army during our civil war, was wounded in the arm, and was imprisoned at Lynchburg, Macon, and Andersonville. He exhibited delusions in regard to his army life. For example, he said people were constantly trying to get his money; that at the skirmish of Wilson's Creek the orderly sergeant and three other members of his own company attempted his life for $80, which they knew he had on his person; and that even Captain Granger, of his regiment, agreed with the Confederate forces to cover a certain spot with sharpshooters, in order that he might send soldiers who had money to that spot for them to shoot at and subsequently rob. The patient intimated, however, that he was too quick for them; saw the opening and refused to go to the spot; and assured me that he noticed that a man who was sent in his place was instantly killed. These ideas of conspiracy to rob him and even to murder him for his money were firmly fixed in his mind; and when proceedings *de lunatico inquirendo* were instituted in order to enable a committee to take such care of him as he seemed indisposed to take of himself he became exceedingly apprehensive. He said he would rather be out of the world than deprived of his money; that he intended to cut down expenses in eating; that a little soup once a day would be enough for him; that a man is no use without money; and that if he did not get it back he would quit eating altogether. He said further that if he "were not taken out a free man, he would be taken out a corpse;" that he would not eat from that time forward.

Six weeks after admission, after a protracted and contested trial, the patient was declared by the sheriff's jury to be sane and competent to manage his affairs, although seven experts of known ability testified to his insanity and to his incompetence and inability to take care of his own affairs. The patient himself had become so contented in his luxurious surroundings, however, that it was not until two weeks later that he could be induced to leave. He exhibited a marked confidence in the institution and its officers and employees, and appeared to be grateful for the considerable improvement which he had made; but up to the present time no pecuniary remuneration has been received from him, and he resumed his former methods of living.

Case IV. is one of paranoia in a young man of wealthy family, in which there were a conflict of expert testimony and a consequent confusing of the jury, leading to the patient's discharge as not insane and subsequent dire results.

Mr. T——, aged thirty-two years, single, no occupation; temperate habits; of strong neurotic heredity. Had made four attempts at suicide prior to admission, and had also been confined in two other hospitals for the insane for varying periods. His maternal grandmother, aunt, and mother were peculiar and eccentric. The patient himself had been peculiar and eccentric since childhood, and had never been able to do anything well in the way of study or work. He was subject to violent outbursts of temper, and had made an engagement of marriage with a lady considerably older than himself, before this lady had become divorced from her husband.

The medical certificates were largely based in this case upon facts relating to the conduct of the patient while confined in institutions prior to the commitment against which proceedings were brought. One of the certificates stated that the patient had always been singular in conduct and suspicious and irritable in manner; that he abused and denounced the body of his father in the room in which his father lay dead; that he brought a number of lawsuits against the trustees of his father's estate; that he was constantly changing his occupation; that he had rudimentary delusions of persecution by his best friends: that on one occasion he waited with a revolver, intending to kill one of his friends whom he believed to be an enemy; that he had on several occasions attempted suicide by shooting and by narcotic poisons; and that he had lately been planning marriage with a married woman.

His history from one of the institutions in which he had been a patient stated that he at one time carried a sword cane to defend himself from attacks that might be made upon him, suspecting a former friend of entertaining designs against him; and he believed his incarceration to be the result of a plot. On one occasion he said that he had a strange sensation, as of a veil drawn over his mind or as if a tape was drawn tightly around his brain inside the skull. He believed that his roommate did various things to test him as to his sanity, but was convinced that this roommate was only the agent of a prominent official at Washington, who was a distant connection of his own family. At one time, he declared, after a quarrel with a man who had long been a personal friend and with whom he at the time was living, that he retired to his room, barricaded his door, drew a pistol, and waited for several hours for his friend to come and attack him, and that had he done this he would have shot him; that he had a perfect right to do so, and that this act would have been defensible both from a moral and legal standpoint.

On admission, he was thoroughly on his guard under medical examination, and not inclined to answer any questions directly. When urged to give his side of the case he talked incoherently about not saying or doing anything that was not reasoning correctly. He talked in an exaggerated and eccentric manner, showing peculiarity in manner of smiling, posing, using his eyes, and emphasizing his words. His pupils were dilated, his eyes somewhat staring, and there was some asymmetry of the face.

Proceedings *de lunatico inquirendo* were begun less than a week after his commitment, and, as the patient could command considerable money, he was enabled to obtain shrewd counsel, who instructed him to allow no medical examination whatever except by such physicians as should be sent or accompanied by his counsel. When the case came to trial his counsel suceeded in eliminating from the testimony the evidence of physicians who had treated him in hospitals, on the ground that they were his family physicians and could not reveal the secrets entrusted to them. The opposing counsel did not take the trouble to overcome this technical point, and did not present expert witnesses. A point was made with the jury by the patient's counsel that one of the men who accompanied him to the hospital owed him considerable money; and he tried to show a motive for the patient's commitment. It was not, however, owing to the strength of the case of the defendant so much as to the weakness of the case of the plaintiff that the verdict of not insane was obtained after a protrated trial, lasting several days.

Immediately following the patient's release by the court he instituted proceedings, suing his brother for $50,000 for malicious persecution. Some time after that he married the lady to whom he was engaged, who subsequently bore him a son.

In July, 1897, application for his readmission was made, on behalf of the wife, by the physicians who made out his original commitment. The case was declined, and he was sent to another institution. The certificate of his commitment there stated that he was delusional, believing that he had been unjustly dealt with; that he believed his wife a princess, though unable to explain why; that he was excitable, suspicious, violent, and dangerous; that he said he had clenched his wife by the throat until she told him things he wanted to know; and that he had attempted suicide several times by inhaling gas and by taking lethal doses of chloral and morphine; further that he grew confused in attempting to carry on a connected conversation, would enter into litigation on the smallest provocation, and spoke obscenely of his wife's daughter by her first husband. Objectively, it was noticed that he had a peculiar staring expression, "wild" fitly describing it; that when alone he was preoccupied, but when addressed quickly collected himself, using good language; but his manner, speech, and expression seemed studied and stilted. He slept well; his bowels were said to be constipated, tongue coated, and breath foul—a chronic condition. Shortly after his commitment his wife took up her residence near the sanatorium and visited him nearly every day; and an account of his condition during his stay there has been furnished me by the superintendent. While there he exhibited exalted ideas and an exaggerated manner: at one time was excitable and at another apathetic, taking little interest in what transpired about him. The daily visits of his wife seemed to perturb him considerably. On the 23d of August, 1897, he attempted suicide by projecting himself head first against the iron bars of his window, sustaining a scalp wound which required sixteen stitches. On October 22d, his condition was such that *de lunatico* proceedings were again instituted, this time by his wife; no difficulty was found in obtaining a verdict of incompetency, and his wife was appointed his committee. She, however, insisted on removing him from the sanatorium, and on November 30th the New York papers contained a long article, to the effect that he had made a violent assault on his valet, attacking him with an axe and inflicting several severe wounds of the head. He was again examined and committed to a hospital for the insane, where he now remains.

Had the proper verdict that the patient was insane and incompetent been found in the first instance, he would have been cared for and protected and the census would not have been increased by the addition of another presumably degenerate offspring.

Case V.—Mr. C——, a man of gentle breeding, good education, and some property, had lived the pace and developed general paresis; in 1895 he was treated scientifically by a prominent alienist of New York. After a few months' mild excitement he improved to such an extent as to resume his customary position in life; but in the spring of 1897 he again became excitable, wrote incoherent letters, threatened acts of violence, and was reckless in regard to his money affairs. He deposited considerable sums of money and articles of jewelry at various places of business in New York: *e.g.*, left his watch at a theatre; a valuable ring at a jewelry store; a solid gold matchbox at a cigar store; various sums of money at cafés and with prominent dealers in flowers, fancy groceries, etc.

It was not, however, until the fall of 1897 that, on account of an assault on a fellow clubman at one of the clubs in New York, he was arrested and afterward committed for treatment, the responsibility for his commitment resting partly on his father, with whom he was not on very friendly terms, and on a reputable firm of attorneys.

While under treatment he exhibited both the psychic and somatic symptoms of paresis. He was at first exceedingly irritable and excitable and violent, exalted in manner and speech like a person exhilarated with wine, expansive in his ideas, extremely talkative, wrote innumerable letters to public men and comparative strangers, expressed many schemes of an impracticable nature, made unreasonable demands, and talked very freely about his most private affairs. The knee jerks were absent; the pupils reacted to distance but not to light; there was tremor of the tongue and muscles about the mouth and eyes, and in excitement there was slight halting at labials and linguals in speech. The patient said he never felt so well in his life; that he could write a million letters a minute, and wanted to sing at one of the institution concerts. He was controlled with tact and the employment of large doses of sedatives, hydropathic treatment, and moderate exercise; and after about five or six weeks the symptoms subsided, and a remission seemed about to be inaugurated. At this time, however, his attorneys instituted *de lunatico* proceedings. The patient at that time would have been willing to compromise his affairs, allowing some authorized person to manage them entirely, provided he was given liberty of person, but his attorneys did not then recognize the advisability of this. All the tangible symptoms that were evident when the proceedings were instituted were the grandiloquent and self-satisfied air, the absence of knee jerks, the Argyll-Robertson pupils, and slight enfeeblement of mind. He was given an opportunity to obtain counsel and allowed to go to New York as frequently as he chose with an attendant, to consult his counsel and to obtain testimony in his behalf. His attorneys attempted to prove that his symptoms and conduct had been entirely due to alcohol. His condition at the time of the trial being one of remission of his disease, it was difficult to prove to a jury that an organic disease and not alcoholism had really existed. The case was therefore compromised by the attorneys before it went to the jury, and the court discharged the patient on a technicality.

The effect of the trial and publicity was very unfortunate and disastrous to the patient. He gradually developed a condition of profound depression; became sleepless, lost appetite, and found it exhausting to take even short walks; and a few weeks after leaving the hospital he attempted suicide by shooting himself in the head.

Had the entire case been managed by physicians without (as it proved) ill-advised legal intervention, is it not possible that a less tragic result would have been attained?

If the constitution did not restrict us to jury trial, some of the evil results of the present system in *habeas corpus* and *de lunatico* cases might, in my judgment, be obviated by trials before commissions comprised of two or three medical men associated with a judge.

However, possibly in the near future some improvement may be obtained by the proposed method of having experts appointed by the court, the idea being that their opinion would be unprejudiced and have greater weight with the jury. But, whatever method is adopted, the importance of unprejudiced testimony by medical men who have cases long under observation cannot be overestimated and may usually be taken as a safe guide and of assistance in the formation of the opinion of associate experts; but no one can fathom the depths of the layman's mind in medical matters.

Blepharitis Marginalis.—Hydrogen dioxide softens the crusts along the edge of the eyelids. Dilute the twelve-volume solution one-half, to avoid pain from contact with the conjunctiva.—S. C. Ayres.

Pneumonia.—Wet sheet frequently renewed when there is hyperpyrexia.—T. Lauder Brunton.

CASES OF CHRONIC AND ACUTE INTESTINAL OBSTRUCTION SUBJECTED TO OPERATION.[1]

By RICHARD J. HALL, M.D.,

SANTA BARBARA, CAL.

In publishing this series of consecutive cases, which I do not hesitate to say constitute the blackest page in my surgical experience, I am influenced by several motives. One is that the series includes several cases of sufficient surgical interest to be placed on record. The second is that, though the record as regards recoveries is very bad, I think such cases should be published. We read constantly in the medical journals reports of isolated cases of operation for acute intestinal obstruction, with or without septic peritonitis; and the cases are almost always successful ones. I believe that the unsuccessful cases, occurring in general surgical practice all over the country and not published, outnumber the successful ones fifty to one, and the patients who die unrelieved and the cause of whose death is marked on the certificate as inflammation of the bowels are still more numerous. And this brings me to my third reason for publishing this record. Though an Eastern man, I am not one of those who decry either country practitioners or Western doctors, for I know that both classes have given us some of the brightest stars in medical science. No man who has read the splendid tributes of Sir Walter Scott in the "Surgeon's Daughter," of Trollope in "Dr. Thorn," and of Ian MacLaren in the "Bonny Briar Bush," can afford to sneer at the country doctor. But nevertheless it does seem to me that this subject of intestinal obstruction and the absolute necessity of early operative interference is not sufficiently recognized in the West. During a very active service of ten years in New York, chiefly as attending surgeon to Bellevue and St. Luke's and assistant surgeon to Roosevelt Hospital, I got the impression that most physicians there recognized the serious character of intestinal obstruction, and, as soon as they found that the obstruction was organic in character, urged operation. In California I have found it different. There are a number of reasons for this. Chief among these are two. In the first place, the people are, on the whole, less conversant with scientific matters and have consequently a greater dread of the knife. Then a physician incurs a greater responsibility in advising operation. If the patient dies unrelieved, the cause was "inflammation of the bowels," and is regarded as an act of God, for which no one is to blame; while if an operation was advised and the patient nevertheless dies, why, it was a "butchery," and the physician who advised the operation is held to be an accessory.

My plea, therefore, is for an earlier recognition of cases of organic obstruction, in which no sane man can expect that treatment by drugs can be of any avail, and for operative treatment before, in chronic cases, the patient is so reduced that any operation must be fatal, and before, in acute cases, intestinal paralysis, gangrene of the bowel, or septic peritonitis has made a fatal result almost inevitable.

In the following report I have separated the cases of obstruction at or above the pylorus from those of the small and large intestine, and include in the former one of pharyngeal obstruction, while in the latter I include one case of strangulated incomplete inguinal hernia in a woman, causing acute intestinal obstruction without evidence of the seat of the obstruction before operation. The cases, however, include all, except those of ordinary strangulated hernia, within the dates given.

[1] This article was written for publication shortly before the author's lamented death.

I. Operations for Obstruction at or above the Pylorus.—Case I.—Stricture of pylorus, due to gastric ulcer; gastro-enterostomy, August 5, 1893; recovery.

R. L——, aged thirty-six, American, single. Previous history: Since childhood, acid dyspepsia, with frequent vomiting and pain in epigastrium. Long intervals of complete freedom, with sudden recurrence of attacks. Fifteen months ago, almost fatal hemorrhage from stomach. Before and after this, frequent attacks of intense pain in epigastrium, when patient would roll on floor in agony for hours. When first seen, one year ago, emaciated, skin and mouth dry, vomited often, frequent attacks of intense pain as above. Ordered peptonized-milk diet, rest, Carlsbad salts (one drachm, t.i.d.). Patient improved much, gained flesh and strength, severe pain ceased, vomiting less frequent. About two months ago began to emaciate; vomiting more frequent and in large quantities. At present emaciation excessive; vomits almost every day intensely acid fluid from two quarts upward; no acute pain; mouth and skin dry; constipation; digestion so slow that curdled milk is vomited eight or ten hours after ingestion; constant thirst; urine scanty, moderate amount of albumin, acid; specific gravity, 1.022. Physical examination shows great distention of stomach. Diagnosis, pyloric stenosis, due to cicatricial contraction.

August 4th, 4 P.M., stomach washed out with boric-acid solution.

August 5th, stomach and bowels having been thoroughly emptied, ether, usual antiseptic precautions. Incision from xiphoid appendix to umbilicus. Stomach much dilated; extends, though empty, to navel. Pylorus attached to liver, colon, and surrounding omentum by old adhesions, rendering Heineke's pyloroplasty difficult or impossible. Adhesions and thickening of mesentery of colon render Hacker's operation unadvisable. Wölfler's operation performed. Anastomosis about one and one-half inches wide; about fifty Lembert-Czerny silk sutures used. Abdominal incision closed with deep and superficial catgut sutures. Occlusive dressing.

December 30th, no general or local reaction followed operation.

On removal of dressing two weeks later, wound healed *per primam*, except small strip where skin sutures had separated and which healed rapidly. Nutrient enemata during first five days; then liquid food, gradually passing to solid. At first vomiting every two or three days, usually voluntary, to relieve gastric distress, and vomitus much less in quantity; then not more than once a week, with constant gain in flesh, health, and strength. When last seen, about one week ago, no vomiting or distress for more than six weeks, general health excellent, works hard and rides long distances, appetite good, and eats anything. Has gained more than forty pounds.

October, 1896, recent reports indicate that patient is in good health.

It may be of interest to mention that exactly the same operation was performed on a dog at the same time, and when it was accidentally poisoned about two years later the opening between the stomach and the intestine showed absolutely no contraction.

Case II.—Carcinoma of pylorus; gastro-enterostomy; recovery.

J. D. M——, aged fifty-three, October 15, 1894. Patient first seen, September 4, 1894. No cancer in family. During past three years constant dyspepsia; severe pain in epigastrium, especially after eating; frequent vomiting, progressive emaciation, loss of strength, no hemorrhage from stomach. Examination: Much emaciated, cachectic. No tumor detected on examination. Ordered lavage of stomach twice daily, milk diet, etc.

October 13th, under lavage and milk diet, vomiting has ceased, pain undiminished; loss of weight continuous, but less rapid (the week before last visit lost over eight pounds; since has lost one and one-half pounds a week). Examination shows a freely movable tumor in right hypochondrium.

October 14th, examination of contents of stomach (Boas' test) shows, after test meal, complete absence of HCl.

October 15th, bowels emptied. Stomach washed out with saturated solution of boric acid just before operation. Usual aseptic precautions. Ether. Median incision. Scirrhus carcinoma of pylorus, involving about two-thirds of stomach. Mesenteric glands involved. Resection being impracticable, selected a coil of jejunum as near duodenum as possible and made a gastro-enterostomy, with anterior surface of cœliac end of stomach, using Murphy button. Actual insertion of button occupied not more than five minutes, but escape of air at one side seemed to require insertion of about six interrupted silk sutures. Abdominal incision closed with silver wire buried sutures and continuous silk sutures of skin. Occlusive dressing.

November 1st, no local or general reaction occurred. After second day patient was able to take liquid and later solid food, without pain or vomiting. Dressing and silk sutures removed after fourteen days. Primary union. Patient has gained flesh and strength, and states that he feels better than for several years.

Final note: The patient died some three months later of general carcinomatous cachexia, but was able to eat and digest solid food to the last without pain or vomiting. The Murphy button, though carefully looked for, was never found, and no autopsy could be obtained.

It is of interest to mention that, just at the time he left the hospital, his wife presented herself, with a rapidly growing round-cell sarcoma involving the whole right upper maxilla. I excised the upper jaw and she made a good recovery, but metastatic growths appeared in the lungs within a few weeks, and she died, without local recurrence, about the same time as her husband. One such case is, of course, no evidence, but, taken in connection with a series of similar cases which I reported some years ago to the New York Surgical Society, it is difficult to avoid the idea of a *contagium vivum* and direct infection.

Case III.—J. E——, aged forty-five, Spanish. December 4, 1896. Gastrostomy for carcinoma of œsophagus. Patient has suffered for some months from difficulty in swallowing. Has had several severe hemorrhages from the œsophagus. Has lately been able to swallow only small quantities of fluid, which is frequently regurgitated. Suffers great pain, pointing to the level of the bifurcation of the trachea, and auscultation during the act of swallowing indicates the same level. No bougie was passed, for fear of hemorrhage. Operation, ether, gastrostomy by Witzel's method. Patient fed by rectum for three days, after which food was introduced by tube. No general or local reaction, and wound healed *per primam*. A month after operation patient was in excellent condition, having gained strength and weight; no pain or hemorrhage. Is unable to swallow, and takes all nourishment through tube.

June 1, 1896, about six weeks ago learned that patient, finding himself able to swallow some food, insisted, in spite of his physician's advice, on removing the tube some days previously; when reported, could no longer swallow and was apparently dying. No leakage had occurred at any time.

Final report: Am told that patient died of inanition about one week later.

Case IV.—Miss L. W——, aged about thirty. Cicatricial contracture of pylorus; pyloroplasty. Patient has suffered from two to three years from symptoms of gastric ulcer; has had frequent hemorrhages, constant and severe pain, and vomiting. When first seen, the day before operation, was very feeble and much emaciated. Could retain only a little barley water. Had retained no food for three weeks. Operation had been urged for some time by Dr. Otto, but refused. Ether. Median incision. An impermeable stricture of the pylorus was found. Pyloroplasty by Heineke-Mikulicz's method was performed, fine silk sutures being used. Stricture was due to a healed ulcer. Patient did not rally after the operation, and died twelve hours later of collapse.

Case V.—Carcinoma of pharynx, gastrostomy, and laryngotomy. F. J——, aged forty-five, single. Previously healthy. Patient noticed a small growth in right side of pharynx three months ago. This has grown rapidly; has recently become ulcerated and extremely painful, interfering greatly with swallowing. Has lost much flesh and strength.

June 18, 1896, examination: Patient very weak and emaciated, and almost unable to swallow, taking only very small amount of liquid food, most of which escapes through the nostrils. An ulcerated new growth occupies the whole right side of the pharynx, extending beyond the median line, involving the tonsil and pillars of the pharynx and right ramus of the inferior maxilla. Both deep and superficial lymphatic glands on right of neck much enlarged. Growth extends down to and involves the larynx, which is almost immovable, and respiration is much affected. Ether. Gastrostomy by Frank's method. Stomach opened at once and nourishment given a few hours later. No leakage occurred, except to a very slight extent, on removing the tube. No reaction and wound healed *per primam*. Took nourishment freely and improved for a time, but three weeks later increasing dyspnœa required laryngotomy. Died from the progress of the disease two days later.

Case VI.—Miss S. Y——, aged eighteen, American. October 9, 1896. Ulcer of stomach, cicatricial contraction of pylorus; gastro-enterostomy. Since childhood, subject to severe attacks of pain in region of pylorus, accompanied by vomiting. Never vomited blood. Pain often so severe that patient would roll on floor in agony. Attacks lasted one to three days; occurred sometimes once a month, or with several months' intermission. Between the attacks, only moderate tenderness over pylorus. Menstruation regular and normal. One week ago patient had similar attack, which has continued to date. Pain partly relieved by moderate doses of morphine, but all attempts to move bowels by enema have failed. On examination, patient thin and poorly nourished, is throwing herself around in bed, screaming with pain, making thorough examination impossible. Pain especially severe in right hypochondrium, where there is great tenderness on pressure. Abdomen moderately distended. No escape of fæces or flatus since attack commenced. Frequent vomiting of apparently pure bile, excited even by a spoonful of warm water. Passes water freely. Pulse, 110; temperature normal. Gave morphine, one-fourth grain, to quiet patient and allow examination. Seen three hours later, when a small, hard movable mass was felt in region of pylorus. Percussion showed stomach dilated to level of umbilicus. Diagnosis of cicatricial contraction of pylorus, due to ulcer. Urged immediate removal to hospital and operation, but parents declined.

October 10th, patient entered hospital. Condition as before, but vomiting more frequent; hiccough; pulse, 120, and varying in quality.

At 11:30 A.M., ether, usual aseptic precautions. Median incision from xiphoid appendix to umbilicus.

Stomach found distended as above, while small intestines were collapsed. Both stomach and small intestines much congested, especially near the pylorus. Gall bladder could be seen, and it and the gall ducts were palpated and found normal. On palpation the lower end of the appendix cæci was slightly enlarged and apparently contained a concretion, but without adhesions or evidence of inflammation. The pylorus was firmly attached to the anterior surface of the right kidney by old adhesions, which it seemed unsafe to break up. At the pylorus was a firm hard mass, about the size of a walnut, obviously either a carcinoma or a cicatricial mass due to an old ulcer. From age and previous history, undoubtedly the latter. Gas or fluid could not be pressed from the stomach into the intestine. As the pylorus could not be brought into view, pyloroplasty was impossible, and a coil of small intestines, six inches from the duodeno-jejunal junction, was brought up and Wölfler's gastro-enterostomy performed, Czerny-Lembert suture with black silk being used, and the opening about one and one-half inches long. The intestine being opened, it was completely empty, while the stomach was greatly distended with greenish fluid. This was evacuated, while the abdominal cavity was shut off with gauze packing. Abdomen closed with deep and superficial silver sutures. Occlusive dressing.

On recovery from ether, pulse was 134, but sank slowly during the next two days to 90. No further vomiting occurred and bowels moved freely from that time on. Patient took liquid nourishment after the second day. Almost every day, however, there was an attack of severe pain, sharply limited to the region of the pylorus, lasting one to three hours, and requiring small doses of morphine. These attacks became shorter and less severe during the first eight days, while the patient gained flesh and strength and seemed otherwise in perfect health. On the ninth night the pain was severe and almost continuous, and toward morning she complained suddenly of intense pain in the lower part of the abdomen, vomited twice, pulse of 120–130, face sunken, skin cold and clammy. Tympanites occurred rapidly and there was obviously perforative peritonitis. Parents refused further operation and the condition of the patient would scarcely seem to warrant it. She died in collapse at 5 A.M., next morning. Abdominal incision was healed *per primam*.

It is a matter of deep regret that the parents absolutely refused a post-mortem, but the history of the case before and after operation makes it, I think, reasonably certain that an unhealed ulcer perforated into the peritoneum. I am sorry that the desperate condition of the patient at the time of operation deterred me from opening the stomach freely, seeking for an unhealed ulcer, and treating it, if found, with the actual cautery, as has been successfully done by Mikulicz.

Of the three cases of gastro-enterostomy, two were treated by suture and one by the Murphy button. All such mechanical aids seem to me inferior to a needle and suture, skilfully used, and the numerous accidents reported with the button would keep me from using it unless the utmost haste was necessary. Two patients recovered entirely from the operation, and one patient apparently recovered from the operation but died on the tenth day from an unforeseen accident. The patient upon whom pyloroplasty was performed, having retained no food for twenty-three days previous to operation, died of exhaustion. Both patients upon whom gastrostomy was performed recovered, but in that case in which the gastrostomy was done by Witzel's method no leakage whatever occurred, even when the tube was removed, while in that by Frank's (drawing out the stomach wall through a small incision, undermining the skin upward to a small incision above the border of the ribs, drawing the cone-shaped portion of the stomach beneath the skin, and fastening it in the upper incision, closing the lower incision) slight leakage occurred if the tube was removed.

In another case I should use a method which I tried on a dog more than a year ago, and found very rapid. Make a small abdominal incision, draw out a cone-shaped portion of the stomach wall, suture the base of this round the edges of the abdominal incision, invert the cone so that it projects into the stomach, and pass a tube into an opening in the apex. The result in this would seem so closely to resemble that of the operation recently published by Mikulicz in the *Centralblatt für Chirurgie*, and really is a modification of Witzel's operation, that I doubt if it can lay claim to being a separate method; but the technique seems to me simpler and more rapid.

II. Operations for Obstruction below the Pylorus.—These cases may be reported briefly, since, with perhaps two exceptions, they are of no great interest, except to enforce the lesson that in cases of intestinal obstruction delay is fatal.

Case I.—B——, male, aged thirty-two; September 27, 1894: acute intestinal obstruction due to band. Constipation for years, with frequent severe colic. Small passage four days ago, after several days' constipation; then intense pain in ileo-cæcal region, tympanites, complete obstruction, constant vomiting. Last twenty-four hours hiccough and fæcal vomiting. Treated with cathartics, injections, and morphine.

September 27th, examination: Condition as above, with evidence of general peritonitis. Ether. Laparotomy. Abdomen filled with sero-pus, intestines congested and covered with patches of purulent fibrin. At junction of cæcum and colon, a band of old adhesion completely occludes the bowel, which does not expand on cutting the band. Entero-anastomosis between cæcum and colon with large Murphy button. Abdomen thoroughly cleansed with many gallons of hot sterilized water. Gauze drainage. Patient did not rally, and died after a few hours. No autopsy allowed.

Case II.—N——, male, aged forty-one; June 9, 1894. Volvulus of ileum. Complete intestinal obstruction for five days. Vomited once, but no other symptoms, except intense pain in the abdomen, relieved by large doses of morphine. Treated with cathartics, high injections, and morphine. During whole time felt well, except for pain, and allowed to take three meals of solid food daily. Walked to carriage, which conveyed him to hospital, on morning of operation.

June 9th. This morning attending physician thought he detected tumor in right iliac region. At 2:30 P.M., symptoms of acute intestinal obstruction. Moderate pain, patient having had much morphine. Abdomen rigid, indicating peritonitis. Temperature and respiration normal; pulse, 90. Ether. Laparotomy. All intestines matted together with fibro-purulent exudation, and abdomen full of sero-pus. Small intestines greatly distended and almost black, and serous coat had given way at two points. Complete occlusion of ileum due to volvulus, three inches from ileo-cæcal valve. Volvulus untwisted. Small intestine opened where serous coat was torn, and contents evacuated. Openings closed with Lembert sutures. Abdomen washed out with fifty-per-cent. warm peroxide-of-hydrogen solution. Gauze drainage. Patient collapsed and died at 1 A.M. Autopsy refused.

Case III.—G——, male, aged seventy-one; February 23, 1895. Intussusception of Meckel's diverticulum. This case, on account of its rarity, deserves a more detailed report. Six days ago, sudden severe pain in abdomen; since that time no passage of fæces or flatus; constant pain, except when under morphine;

continued vomiting and hiccough. Treatment by cathartics, enemata, and much morphine. Temperature said to have been about normal and pulse not over 80, until this morning, when symptoms of collapse appeared and pulse was 120. Last enema when returned contained mucus and blood. Examination: Pulse, 120. Constant hiccough and vomiting. Abdomen soft; no muscular rigidity or tympanites. Pain and tenderness in right iliac fossa, but no tumor detected. Patient obviously much under the influence of morphine. Diagnosis: Acute intestinal obstruction, probably due to malignant disease of the cæcum or to intussusception. Ether. Incision in right inguinal region. Abdomen contained large amount of bloody serum, and intestines were intensely congested and covered with purulent lymph. There was an intussusception, involving about sixteen inches of the ileum, which had passed through the ileo-cæcal valve, and was already gangrenous at the point of contact with the cæcum. Resection of the cæcum, and about two inches of the ascending colon and of the ileum about four inches above the gangrenous portion. Attempts to unite the divided ends of the intestine with Murphy button failed, because intestine was so soft the thread cut through at once. Established artificial anus, flushed abdomen with hot sterilized water, and used gauze drainage. Patient never rallied, and died in about twelve hours. No autopsy allowed.

Examination of specimen showed a Meckel's diverticulum, sixteen inches from the ileo-cæcal valve, and four inches long. This had become intussusepted, not turning inside out, but inverting four inches of intestine. This mass formed a second intussusception and passed through the ileo-cæcal valve, dragging several inches of small intestine with it. The diverticulum was completely gangrenous, and the four inches of small intestine surrounding it (and invaginated in the small intestine just below) partially so, while the ileum above was also gangrenous, where it entered the ileo-cæcal valve, and the whole lower portion of the small intestine was so softened as to tear at the slightest touch.

Case IV.—A——, male, aged twenty-eight; May 22, 1895. On May 19th applied to a physician on account of pain and cramps in stomach and bowels. History before that time not known, but had probably been sick some days. When seen May 22d symptoms of intestinal obstruction, intense pain in abdomen, face pinched, pulse rapid and small, constant stercoraceous vomiting. Abdomen tympanitic and flanks dull Ether. Laparotomy. Abdomen contained much fæcal matter; intense suppurative peritonitis. Volvulus of small intestine apparently favored by contraction of part of the wall, probably due to healing ulcer. Perforation above this point utilized to empty the bowel, and then closed by suture. Untwisting volvulus restored calibre of bowel, and a few sutures were introduced to avoid recurrence. Toilet of peritoneum. Patient did not rally and died a few hours later. Autopsy refused.

Case V.—Mrs. H——, aged sixty-eight; June 20, 1896. Acute intestinal obstruction due to strangulated incomplete inguinal hernia. Three weeks ago severe pain in abdomen, with vomiting; since that time complete intestinal obstruction, except that once or twice small quantity of flatus escaped. Treated with cathartics, enemata, and morphine, but constipation pain, and vomiting continued. Two days ago stomach washed out, and since that time patient has absolutely refused food or liquid, and vomited only occasionally. Examination: Emaciated woman. Distended coils of intestine can be felt moving beneath relaxed abdominal walls. Pulse rapid and feeble. Temperature slightly subnormal. Face gray and sunken. No tumor found. Ether. Incision in left inguinal region, with the intention of forming an artificial anus. No sign of peritonitis. A coil of distended intestine and one collapsed were found side by side, and, being traced downward, an incomplete right inguinal hernia was found. Incision protected by gauze, and operation for strangulated hernia performed. A knuckle of gut was found barely projecting through the internal ring. No evidence of peritonitis, circulation of strangulated portion quickly restored, peritoneum smooth and shiny, no fæcal odor, peristalsis active, and only about two-thirds of the gut was included in the strangulation. Intestine returned and Bassini's operation with silver sutures done. Inguinal incision closed. Patient rallied well from operation, retained nourishment, and did not vomit until one hour before death. Bowels moved freely and often. There was no rise of temperature, but the pulse became more rapid and feeble, and patient died, seemingly of exhaustion, two days later.

It seems almost incredible that a patient should be allowed to go three weeks with intestinal obstruction before calling a surgeon, but at almost the same time and under the care of some of the same physicians I had a case of acute appendicitis in a woman, of three weeks' duration. An abscess had formed and emptied itself through the inguinal canal into the cellular tissue early in the disease, and when I saw the case the whole cellular tissue from above the umbilicus down to and including the labia majora was a stinking gangrenous mass, nearly four inches thick, while the skin was gangrenous in patches as large as one's hand. In spite of free incisions and removal of as much sloughy tissue as possible, the patient died of septicæmia a few days later.

A few years ago I operated on a similar case, of six weeks' duration, in an old lady, in whom the whole cellular tissue of the thigh, from the groin to below the knee, was gangrenous and infiltrated with pus and fæces. Happily this patient, after enormous incisions and removal of the sloughing tissue, recovered.

Case VI.—Mrs. A——, aged forty-two; January 30, 1895. Carcinoma of pancreas; acute miliary carcinosis of the peritoneum. Patient in perfect health until five days ago, when sudden intense pain in abdomen, first in region of umbilicus, later in right iliac fossa. Since that time constant vomiting of greenish fluid. No escape of fæces or flatus, in spite of cathartics and enemata. Temperature, 100° to 101.5 F.; pulse rapidly increasing in frequency, until this afternoon it reached 150. Examination: Condition as above. Very stout, well-nourished woman. About three inches of abdominal fat made examination difficult. Vaginal examination negative. No tympanites. Abdominal muscles not rigid. Marked tenderness in right iliac fossa; slight tenderness over whole abdomen. Diagnosis: Appendicitis or acute intestinal obstruction, probably the former. Ether. Incision in right inguinal region. Large amount of bloody serum escaped. Appendix normal. Incision prolonged upward. Carcinoma of pancreas, involving whole gland and mesenteric glands. Whole intestinal and parietal peritoneum covered with snow-white specks, each about the size of a pinhead, evidently a miliary carcinosis. Abdomen cleansed and closed. Patient regained consciousness and suffered no pain, but pulse became more rapid and feeble, and she died about twelve hours later. Autopsy showed condition as above and large amount of sero-sanguineous fluid in abdomen. This was of course not a case of intestinal obstruction, but I include it because the symptoms so closely simulated that disease and because the case itself is one of rare and unusual interest.

Case VII.—Miss M——, aged about thirty-five. This was merely a case of chronic intestinal obstruction, becoming finally almost absolute, and due to a

carcinoma of the rectum high up and entirely inoperable when first seen. Left inguinal colotomy was done, and the patient lived in comparative comfort for several months before succumbing to the progress of the disease.

I publish my very unfavorable record in these last seven cases, chiefly to call attention to the following points. Temperature is of very little value as a guide in intestinal obstruction, unless it be a subnormal temperature, due to gangrene, perforation, septic peritonitis, etc., causing rapid collapse. The important symptoms are pain, either general or fixed, when it may be either at the point of obstruction and in some quite different part of the abdomen, obstinate constipation, vomiting, and steadily increasing rapidity of the pulse, which is generally small and wiry. Every man who does much abdominal surgery knows that vomiting and rapid pulse are the two symptoms which cause him the gravest anxiety after operation. To these may be added the expression of mental anxiety, so graphically described by Erichsen, in the earlier stages, and the gray, sunken, and pinched appearance of the face when gangrene, perforation, and septic peritonitis have occurred, in the later stages. The board-like rigidity of the abdominal walls, when septic peritonitis exists, is a valuable guide, but may be entirely lacking. Several of the most valuable guides—pain, local tenderness, the anxious facial expression, abdominal rigidity, and to some extent also the character of the pulse—may be completely masked by morphine, and therefore I protest strongly against its use in such cases, unless it be to give temporary relief while preparing for operation. With the aid of morphine a patient may be guided quietly and comfortably to his grave, and, because he feels so well, will believe himself to be almost convalescent when the belly is full of pus and fæces.

So many cases of coprostasis, especially in women and old men, simulating intestinal obstruction, occur in the practice of every physician, and are promptly relieved by a brisk cathartic or a stimulating enema, that we cannot condemn a resort to these measures in the early stages when no objective symptoms indicate an organic obstruction. But once these measures have failed, it should be remembered that a few hours may suffice to cause intestinal paralysis, gangrene or perforation of the bowel, and septic peritonitis, when the patient's chances become very small indeed.

One word more in regard to the question of autopsies. It may be noticed that in the foregoing cases in only one or two could an autopsy be obtained, though in several it would have been of great value and interest. This is a prejudice similar to that against dissection, which formerly made the study of anatomy so difficult, and which does not exist to anything like the same extent in communities more highly educated in scientific matters. It seems to me to be the duty of the profession, by personal influence, to endeavor to eradicate this prejudice as far as possible.

A New University College Hospital Building.—Sir Blundell Maple, head of probably the largest furniture firm in the world, has just presented the sum of $500,000 for the purpose of building a new hospital in connection with University College, London, the present erection being altogether inadequate to the needs of the population of the district in which it is situated. The Prince of Wales, when laying the foundation stone of the new building and in acknowledging Sir Blundell Maple's munificent gift, remarked that it was the largest sum given to the sick poor of London since Thomas Guy in the seventeenth century established the hospital which bears his name. *London Times.*

THE CURE OF WRITERS' CRAMP AND TELEGRAPHERS' PARALYSIS.

By S. H. MONELL, M.D.,

BROOKLYN, N. Y.,

CHIEF INSTRUCTOR OF THE BROOKLYN POST-GRADUATE SCHOOL OF CLINICAL ELECTRO-THERAPEUTICS AND ROENTGEN PHOTOGRAPHY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

This is a subject which concerns the author with the direct personal interest of one who has had the disease himself. After four and a half years of conservative observation of the results of many experimental variations in electrical treatment, I am now willing to state that writers' cramp is curable in all stages and in every uncomplicated case. This is also true of similar affections which result from overuse of the arm muscles. They are definitely curable by methods of mathematical exactness which may be successfully employed by any physician who understands electrotherapeutics and writers' cramp. They are simple and rational methods, without mystery or inconvenience to the operator.

I have waited for the confirmation of time and the better instruction of an enlarged experience before taking any positive ground or expressing any hope of restoring an advanced case, but, having finally worked out the true principles of treatment, I find that results are as certain in the worst cases as in the simplest; they require longer treatment only. I have taught the principles and technique to physicians in my clinic, who can confirm what I shall here say, and any telegrapher or penman or pianist who makes a personal test becomes convinced of success in a single week. No argument is required to sustain any theory about the matter, for the results are self-evident and unmistakable.

There is but one fault to find with the plan of treatment—it is not so rapid as could be wished; but, since the loss of power in the arm has been a slow process, it must probably be a slow process to restore it, and I doubt if it will ever be possible to cure a severe case of cramp or paralysis in one or two weeks' time. Relief will begin at once and commencing stages may obtain a practical cure in two weeks, but men who have been totally disabled for from one to ten years cannot expect to send good Morse or write with ease in less than from forty to sixty treatments.

When I began the study of these diseases (all of which may be grouped under the one head of "writers' cramp") I found them described by medical authors under the head of "nervous diseases," and I do not now recall the discovery of any really useful therapeutics for well-developed writers' cramp in all my searches in medical literature. When I adopted the suggestions of other medical writers, I failed. When I treated the separate symptoms locally, I also failed; but when I ignored symptoms (except pain) and applied myself steadfastly to the improvement of nutrition, I began to succeed. At first I succeeded only with very mild cases, but in time and with increasing experience I at length worked out the true principle upon which absolute and unequivocal success is based.

So long as I was misled by the inaccurate teachings of neurology in regard to the nature of this disease, I tried method after method in vain and felt convinced that a radical cure of severe cramp was wellnigh impossible. I saw and talked with the author of a much-advertised method of "special massage" when he was in this country some years ago, witnessed his demonstration at the New York Academy of Medicine, and had his method applied to my own arm, but was left in doubt as to its actual value to any one but himself. Since understanding the disease better it is plain to me that massage aims in the right direction, but is a laborious and unprofessional method which hits the mark at random if at all. Space

will not permit me to discuss the merits of the different plans of treatment with which the persistent study of four and a half years has made me acquainted.

The first thing to consider is the true nature of the disease. It is not a "neurosis," but is obviously a state of impaired nutrition. When a healthy person fatigues his arm by unusual and severe work, rest will take away the lameness and exhaustion; but if overuse is continued day after day, the nutrition of the tissues does not keep pace with the waste of wear and rest becomes less and less effective. When telegraphers, writers, typewriters, pianists, or others work at a rate of speed which is beyond endurance, there develops a state of chronic fatigue, which is the disease. The most numerous class affected by writers' cramp have worked in the press association offices in our large cities, where telegraphing on heavy wires at a high rate of speed breaks down in a few years a considerable number of men. From the fact that the disease does not exist until the muscle fibres cease to regenerate themselves by rest, it is a contradiction of terms to say that "rest" will cure it. It is the custom of most physicians to advise patients to "rest," but this advice is conclusive proof of ignorance of the disease or at least of any remedy for it. If "rest" was a curative measure ninety-five per cent. of the telegraph operators now affected would get well, for all of them can report periods of rest of from one to fifteen or more years. I shall here state the exact bearing of "rest" upon the subject, for the benefit of other physicians, for telegraphers themselves will never consult a second time a practitioner who advises them that rest will restore a "lost grip."

In the very earliest stage of acute fatigue the muscle fibres still retain the power of self-regeneration, and rest permits nutrition to become normal again. When fatigue advances to the persistent stage of pains, lameness, heaviness of the arm, and marked lack of power, a reasonable rest will relieve the symptoms, but they will return again when work is resumed. Rest has no permanent curative value and does not make the arm any better.

In all the later stages of cramp and increasing paralysis down to the time when the operator is just able to jab at a key with one finger, "rest" will not only not cure the arm, but the operator who stops work for a few months in the hope of betterment will find his arm more useless when he tries it again. It degenerates during rest when it has reached this stage of impaired nutrition.

Exercise is another overrated measure. Many think it will prevent the disease, and fully one-half of the operators I have treated have attended the gymnasium or kept themselves in powerful muscular condition. Exercise will neither prevent nor cure telegraphers' paralysis.

It is also certain that writers' cramp cannot be cured by drugs, and in all medical literature there does not exist any account of a satisfactory remedy which gives a certain and good prognosis.

"Electricity" has been vaguely recommended by various authors, and, although it has been employed by a diversity of methods and with indifferent results, it was the remedy to which I first turned with hope and adhered to through many disappointments, until finally the correct principles of its application became clear. From the moment I comprehended that the disease was a peripheral impairment of nutrition, it became a mere matter of restoring nutrition to normal to remove all the troublesome symptoms of the disease. Of these symptoms the cramp previously baffled me for over three years, but within a year and since the discovery of a more rational method it has lost its former hopelessness. The worst case of cramp can be cured.

The principles of curative electrical treatment are simplicity itself. The arm is first subjected to a gentle warming-up application to quicken the circulation, as the preliminary canter warms up a racehorse before he enters the race. The arm is next subjected to general nutritional muscular contractions, regulated in energy and number by the tolerance of the tissues. Finally the arm is given a refreshing, restful, nutritional application, which leaves it at the close of treatment invigorated, buoyant, and elastic. The total treatment requires about ten minutes, and every moment and every detail of each application aims at improving the nutrition of muscle fibres.

Every physician who is well taught in the production of special therapeutic effects by electric currents will understand that nutritional and refreshing effects can be produced in more than one way. The technique of counter-irritant applications, nutritional applications, sedative-tonic applications, and muscle-contracting methods by means of static currents is fully described in chapter xxvii. of the author's "Manual of Static Electricity in X-Ray and Therapeutic Uses," and probably every physician is also familiar with the "refreshing" action of the galvanic current. The main thing is the comprehension of the fact that the only indications are to relieve pain and to improve nutrition, and nature will take care of all the rest. As the disease is essentially a peripheral degeneration of nerve and muscle nutrition, the cure depends upon restoring the nutritive processes to normal. When nutrition is restored all symptoms disappear.

In the early stage of easy fatigue with disordered sensations, the muscular achings and sense of heaviness are relieved by the first treatment and complete recovery is established in about two weeks. In the second stage of more marked distress in the arm, constant fatigue, and weakness, with or without pains, about twenty treatments will restore the arm to practical and comfortable work. Improvement begins with the first treatment and the arm feels natural after the first week, though a longer time is required to restore full power. In the third stage, from the time when work begins to be very difficult down to the time when the operator is barely able to work at all and can only handle a light wire by exerting his entire will, a rapid improvement will be gained in a week and the arm will be quite comfortable in a week more, but the return of strength will require about forty treatments. When paralysis, cramp, and spasm have only recently begun, the results of treatment will be the same as those last stated. When the operator has completely lost his grip for one or more years and can no longer look at a key without a cramp, or when the arm cramps with the pen after writing but half a dozen words, the arm will improve to a state of comfort without work in a week; it will be able to do a little light work in two months; it will be practically restored to normal nutrition in about fifty treatments, and thereafter it will continue to improve without treatment and must be again broken in to its occupation by gradual increase of the daily work, just as an arm is broken in when any operator resumes active employment after one or more years away from a key.

In all these cases improvement continues long after the electrical treatment stops. The entire general health of the patient is built up by the treatment. If the left arm is also affected it improves at the same time. An operator who overtaxes himself on a long wire can keep his arm in working order for many years by returning for a couple of weeks' treatment every one or two years. There is no operator, however fine he may still think his arm, who has done heavy work for a term of years, but can by a dozen treatments be improved so much that he will be astonished (probably improved twenty-five per cent.).

The above conclusions express the average results

of my clinical cases, and yet convey but a poor idea of the satisfaction afforded the patient by the immediate comfort imparted to his arm and the general improvement in his health entirely apart from the actual recovery of the grip. In these cases the arm is often affected with pains, numbness, sense of weight, coldness, and other distressful sensations which impair sleep and render the patient uncomfortable even when writing or telegraphing has been suspended. These symptoms vanish very quickly.

More than this. The treatment itself furnishes the barometer of the condition of the arm at any given time. When the patient makes his or her first visit to my office, no verbal account of symptoms can define with equal clearness the stage of degeneration that is expressed by the muscular reaction to a single spark upon the ball of the thumb. During the gradual process of improvement the increasing quickness of muscular contractions sets forth the patient's state as accurately as the clinical thermometer expresses fever. The methods, in fact, are methods of precision, and the results are so certain that they are only a question of technique and perseverance. While rest during the early part of treatment is an advantage, yet most of my patients have kept on with their work, and as soon as the cramp is conquered I advise them to give the arm some use any way. There are exact signs by which progress or the reverse can be measured, and a rational management of the arm is easily directed.

Some will now ask what current should be employed. During my hundreds of trial methods of technique I have employed all three of the chief medical currents—the high-tension induction coil, the galvanic, and the static—and have demonstrated that either one of these can be so handled as to benefit a recent case or even finally to conquer an obstinate case. But to obtain the best results in the shortest time two currents are needed, the galvanic and static. Each of these permits certain applications producing special effects which are unique and cannot be quite duplicated by any other resource in medicine. It is now apparent that poor results reported by so many have been due to the same cause as my own early failures—to wit, poor technique, directed symptomatically. The certainty of repairing these arms by a correct electrical technique is now so clearly demonstrated and is done in so satisfactory a manner that we may well wonder that writers' cramp was so long regarded as incurable. I recall my great personal anxiety about my own arm at the time when the author of special massage treatment was here, and I felt extremely disappointed to have the only man in the world then claiming to know how to cure the disease fall short of our hopes in his alleged demonstration. Year in and year out since then I have held steadily to a purpose, to work out the remedy if possible, and in the correct use of electrical currents the remedy is found.

In stating here, as I positively do, that even the most advanced stages of this disease are entirely curable, an explanation is due to readers of my formerly published remarks. In the chapter upon writers' cramp in "The Treatment of Disease by Electric Currents" I have said:

"It is, however, difficult to 'cure' the total disability stage of writers' cramp so that regular work can be resumed and maintained. I have never been able to conduct a case in this late stage to a satisfactory conclusion, possibly for the reason that such patients have not persisted in treatment. I have attempted a variety of sedative and antispasmodic methods of electrical treatment for severe and persistent cramp, but as none has proved curative it is useless to describe them here. The best results appear to be obtained by simply continuing for a much longer period the methods that afford relief in the earlier stages."

The chapter from which this extract is taken was written a full year ago, although, through publishers' delays, the book has been in print but a few months. I had not then solved the entire problem of treatment, and I stated the best I could do with the technique then described. It is my custom conservatively to understate results in what I write about medical electricity, owing to the frequent charge that the merits of electricity are exaggerated. What, however, may appear an exceptional result when one uses a poor technique may become very commonplace and inferior to average results when experience has taught the same person a better method. This has been my own case in the treatment of telegraphers' paralysis.

In closing, I will add that the permanence of improvement is very satisfactory and all patients who have given me reports of their condition have continued to improve after treatment was stopped. One operator, whose treatment was begun by me on December 5, 1893, had been totally disabled for two years and had lost about half the use of his left hand also. He had seventy-two treatments, the greatest number I ever gave any case of telegraphers' paralysis and writers' cramp, and he continued to gain for a year afterward. I lost track of him until a few months ago, when he reported that he had been able to take a position again in a press association office and was "using his arm for all purposes." He now tells me that he thinks of entering the telegrapher's tournament which will shortly be held in New York City.

865 Union Street.

Progress of Medical Science.

X-Ray Applied to Fractures of the Lower End of the Radius.—Kahleyss has examined sixty of the above fractures—mostly recent—by the Roentgen ray (*Zeitschrift für Chirurgie*, Bd. 45, November, 1897). As a result of these examinations he has concluded as follows: True epiphyseal separations do not occur late in childhood. Fissures do not occur so often as has formerly been thought. True fractures either do or do not involve the whole breadth and thickness of the bone. The first form occurred in eighty-nine per cent. of the true fractures, and was either single (sixty per cent.—transverse, oblique, angular) or multiple (twenty-nine per cent.). The latter form (*i.e.*, the fracture not going completely through the breadth and thickness of the bone) consists of a fracture of a portion of the styloid process, sometimes with a breaking off of the dorsal articular edge. The most frequent complication of the radial fracture is fracture of the styloid process of the ulna (in seventy-eight per cent. of the cases). Regarding the mechanical etiology of radial fracture in this portion of the bone, it sometimes is produced by force and counterforce alone; it is, however, generally brought about by a combined influence of both radius and ulna.

Etiology and Operative Treatment of Tubal Gestation.—In this interesting article Dührssen describes twenty ventral and fifteen vaginal cœliotomies, two cases of posterior colpotomy, and three vaginal total castrations for tubal gestation, and gives the results (*Archiv für Gynäkologie*, Bd. 54, H. 2). In those cases alone in which the tumor reaches some distance above the pelvic brim does Dührssen advise ventral cœliotomy. The advantage of vaginal cœliotomy is the comparatively small operation as opposed to a laparotomy; cure, healing of the wound, and recovery are more rapid by this method; shock is less; abdominal incision through a fat abdominal wall often causes ventral hernia, which hernia may later lead to serious complications. He describes very thoroughly his vaginal

technique. He advises the drawing out of the tumor with broad or pointed clamps, since catgut ligatures may cut through or tear off the tumor. He, further, rarely does a vaginal fixation after the extirpation; he also says that the abdomen or vagina should be entirely sewed up, in order to prevent adhesions between uterus and vagina, which cause complications in later pregnancies and labors. He advises extirpation of the tube in tubal gestation, even when no hemorrhage exists and when pain alone is present; for even after the death of the fœtus dangerous hemorrhages may occur. He speaks against the killing of the fœtus by morphine injections. Etiologically, Dührssen considers tubal disease, particularly gonorrhœal infection, as the most frequent cause of extra-uterine gestation. Other causes are tubal polyps and puerperal atrophy of the tubes.

Potassium Sulphate and Cirrhosis.—At the meeting of the Academy of Medicine, held on March 22d in Paris, M. Richet discussed the various observations which had been communicated by M. Lancereaux confirming the part played by sulphate of potassium in the production of cirrhosis. He showed that in the major part of his observations he had dealt with wines only slightly plastered. Wine is most often plastered in the district of the Midi, and it was therefore necessary to examine the frequency of cirrhosis in that district. It had been argued that a large number of French wines contained as much as from 4 to 6 gm. of potassium sulphate per litre, and this assertion had had a most disastrous result on the sale of French wines, especially in foreign countries and on account of the somewhat unfair competition of German and Italian wines. In 1851 a regulation, which was re-enacted in 1880, forbade the plastering of wines to any extent above 2 gm. of potassium per litre. In 1891 the Loi Griffe laid down anew the same propositions. Shortly afterward, in 1892, M. Richet was sent into Spain to examine and report upon the plastering of Spanish wines. Of fifty-five samples examined, forty-four gave a result of less than 1 gm. of potassium sulphate per litre. Before this date, however, the plastering of Spanish wines was very heavy, and they often contained as much as 6 gm. per litre. In Paris, on the other hand, the amount of plastering is small. Even before the regulation of 1891, the mean amount of sulphate of potassium was only 2.5 gm. per litre, and the figures have now fallen to 1.4 gm. Before the regulation of 1891 the municipal laboratory found out of sixty-four hundred samples only eighty-five which contained 3 gm. of sulphate of potassium per litre. Since the passing of the law the figure has fallen until the highest amount is only 2.5 gm. per litre. There is, therefore, no reason to think that the intoxicating qualities of the wine are due to sulphate of potassium. With regard to the question whether alcohol is responsible for the occurrence of cirrhosis, M. Richet recalled the important investigations of Hanot and his pupil Boix, who found that vinous intoxication is markedly increased by various acids, notably the fatty acids, which are produced in the various dyspepsias so often caused by the abuse of wine. Wine acts on the liver by the alcohol which it contains as well as the acids, in addition to the acids produced by gastric fermentation. M. Lancereaux, having noticed for many years that sufferers from cirrhosis were almost always wine drinkers, sought to discover what was the special toxic element in wine. He thought that acids might be the reason, but made no experiments on this point. On the other hand, he did make experiments with sulphate of potassium, and found that by giving small daily doses to animals he could produce in them a cirrhotic condition exactly similar to that which is found in the cirrhosis of drunkards. M. Lancereaux is therefore, he thinks, correct in considering that sulphate of potassium is to blame in the production of the cirrhosis of drunkards.

Excretion of Micro-Organisms by the Secreting Mammary Gland.—Drs. Basch and Weleminsky have experimented upon animals to study the power of the mammary gland in the above connection (*Berliner klinische Wochenschrift*, 1897, No. 45). The animals used for experimentation were guinea-pigs. They at first tried non-pathogenic germs—the bacillus cyanogenes lactis and bacillus prodigiosus, each of which grows at the bodily temperature and multiplies in milk. It was easily proved that these two forms of bacteria were destroyed in the blood and that the milk always remained sterile. Pathogenic bacteria were then tried. The bacillus anthracis, when introduced by vaccination into the bodies of six guinea-pigs, was not found in the milk. With the bacillus pyocyaneus the following procedure was carried out: Five guinea-pigs were injected intravenously with a pyocyaneus agar culture, one to three days old. In all cases the bacillus was found in the milk five to eight hours after the injection. The experimenters believe this result to have been due to smaller or greater hemorrhages which were found in each animal; through these hemorrhages not only are the germs carried out of the blood-vessels, but the protecting epithelial covering of the mammary gland is also destroyed, thus bringing the germs into the lumen of the milk ducts, where the germs mix mechanically with the milk. It is, then, to be expected from the above that germs which do not produce hemorrhages (not counting those that produce cell necroses and abscesses directly in the breast) will not appear in the milk. Thus far experimentation has borne out this statement. Typhoid, cholera, and diphtheria germs were likewise injected intravenously, but in every case the milk remained sterile, even though the germs were found for some days in the blood. In tuberculous cattle it was found by the investigators that one-fifth of the cows in whose milk tubercle bacilli were found had no local disease of the udder. It must be remembered, however, that small tuberculous foci may have existed which were not macroscopically evident. As to whether a certain infection can be carried by the milk of an animal must be an individual matter; it depends upon the animal in question, and also upon the infectious disease from which the animal is suffering.

Treatment of Tabes Dorsalis.—Eulenburg states that a few cases of tabes are cured or greatly improved; of course only functionally and not in the anatomo-pathological sense. This improvement occurs by the institution of the most varied methods of treatment. Revulsives or the use of nitrate of silver the writer considers of no use (*Deutsche medicinische Wochenschrift*, 1879, Nos. 4 and 5). Empirically electrotherapy, balneotherapy, hydrotherapy have undoubtedly been of service in some cases. Regarding the antisyphilitic treatment of tabes, Eulenburg states that two things have been proved: Cases of undoubted syphilitic tabes can be improved or even "cured" without as well as with antisyphilitic treatment, while the specific treatment itself, in the majority of cases, is followed by but slight improvement; and, secondly, antisyphilitic treatment can *per se* do damage at times. Medicine can ofttimes relieve tabes dorsalis symptomatically. Of greatest importance is the surgical, kinetic, and mechanico-orthopædic treatment of the disease. Operative nerve stretching has not been tried. The various methods of suspension, which all tend to stretch the spinal cord, and apparatus of support have in mild cases produced great improvement, namely, in the ataxia, the lancinating pains, the anæsthesia, and the bladder symptoms.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE PREVENTION AND CURE OF YELLOW FEVER.

IN view of the intense interest which is now manifested in the study of means for the prevention and cure of yellow fever, it is gratifying to note that some progress has been made toward the desirable ends in view. Dr. Giuseppe Sanarelli, whose investigations into the cause of this disease have received so much attention, has by no means been idle in prosecuting his investigations in a practical direction. His discovery of the yellow-fever microbe two years ago was followed by long-continued and finally successful efforts to produce a serum by the usual methods of inoculating animals, preferably the horse and ox, with repeated doses of the poison. His experiments with this alleged curative agent, as detailed in a recent issue of the *Annales de l'Institut Pasteur*, are extremely interesting, although as yet by no means conclusive. It is a matter for some surprise to note that according to his observations the rationale of the action of this serum in no way corresponds with that of antitoxin in diphtheria, as he declares that he has not discovered thus far any antitoxic substances in vaccinated animals. He feels warranted in the opinion, therefore, that the icteroid bacillus is directly destroyed by the injection. Whether or not this theory is tenable on the present basis of bacteriological investigation is a matter of but small moment compared with the direct and practical applications of his methods of prevention and cure. Making all due allowances for the difficulties naturally attendant upon initiative experiments, the results thus far obtained, by reason of the small number of patients treated, can be viewed only in the light of a report of progress in a promising direction.

Everything seemingly depends upon prompt and early treatment, as after a certain period the rapid accumulation of the poisons forbids the hope of cure. This is particularly the case when kidney complication with its accompanying suppression appears. In connection with the intractability of this complication it may still be a question whether or not the serum is yet of sufficient strength to meet all its alleged requirements, as cases are reported in which actual polyuria followed serum injections. The observations were carried on principally in the State of Saõ Paulo in Brazil, where the fever, feeding on unacclimated emigrants, is particularly virulent and fatal—the mortality in some instances ranging as high as eighty and ninety per cent. Sanarelli reports as the result of his treatment but six deaths out of a total of twenty-six cases. This is certainly an excellent showing and warrants further study in the hope of confirmation on a more extended scale. Certain it is that as yet there is no particular method of treatment founded on the many theories of causation of the fever which can guarantee such a ratio of cure. Although the author claims benefit for the treatment only when used in the first stages of the disease, there is no reason for despairing of still better results when the system becomes perfected and the means to the end are proportionately elaborated. IN all good things which belong to long and patient work the best that one can hope for is a reasonably promising beginning.

Sanarelli's observations regarding the possibility of preventing the disease are markedly more encouraging and deserve corresponding interest and attention. For instance, his report of the results of preventive inoculation in a jail at Saõ Carlos do Pinhal, where the fever broke out in February last, are quite significant and encouraging. All the convicts had been directly exposed to the infection by one of their number, who was found suffering from the fever. The inmates were subjected to the serum treatment and all alike escaped. As no deaths have been attributed to the direct action of the injected substance, and as there have been no systemic disturbances other than those associated with a temporary rise in temperature, it would appear to be perfectly safe to follow the lines of the distinguished discoverer in more extended directions, in the hope that the results may be correspondingly confirmative. If half of what seems to be promised is gained, we shall have taken a long step forward in combating one of the greatest scourges of modern times.

THE RED CROSS AND THE ARMY.

IT was almost inevitable that there should be some friction between the medical staff of the army and the officials of the Red Cross in Cuba, and we are not surprised therefore to read in the daily press more or less colored accounts of their differences. One account, written by a member of the Red Cross at Santiago, says that the army officers received his advances politely, but rather stiffly, admitting that they did not have many luxuries for the sick, and signifying their willingness to accept a few things to help them out until their own supplies arrived, but declining all offers of doctors and nurses. "Refused by our own people we next called on General Garcia of the Cuban army and were most cordially received, his medical men being only too glad to accept all we had to offer. So the next morning our four Red Cross nurses and Sister Bettina went over to the Cuban hospital, which was as repulsive and forbidding a place as can be imagined, and began work. The house and patients were astounded and transformed with such a baptism of soap and water as never was heard of before in this benighted region; and by afternoon that little hospital was one clean spot in town, and scoffers

became believers, and army officers became gentlemen who doffed their hats to our demure drab little women, who believe that cleanliness is the first essential to healthfulness."

After describing the far from luxurious accommodation for our own sick and wounded, the writer continues:

"Of course the contrast between the Cuban and our army hospitals could have but one result, and the army surgeons are now willing and eager to have us on any terms we may suggest, and are constantly asking for more than we are prepared to give.'

Any one reading this account with an open mind will probably see at once the causes of this little want of harmony. To put it in unconventional language, the Red Cross is cocky and the army is uppish. The military surgeons are naturally not wildly pleased to have civilians step in and do for the sick soldiers what the medical department of the army, with its necessarily limited appropriation, is unable to accomplish, and especially is this interference unwelcome when it is accompanied by a smile and a there-now-see-what-we-can-do air. In the army the maintenance of discipline is absolutely essential, in the hospital as well as in the field, and the treatment of sick and wounded soldiers by civilian surgeons and nurses, who have delicacies to distribute, cannot but tend to diminish the authority of the army surgeons over their patients. Sick men are like children, their affections and their regard go out to those who give them "goodies." The Red Cross Society, on the other hand, claims that its aims are purely benevolent, that it seeks only to relieve the sufferings of the soldiers, and that it does so through private contributions without calling upon the government for anything but permission to perform its humanitarian labors.

The main objects aimed at by the members of the Red Cross and the surgeons of the army are identical, and the differences between the two bodies are but slight and should be easily adjusted. Let the Red Cross officials remember that when they work within the lines of our forces they must be subject to the regularly constituted officers of the army, and must act in perfect harmony with them. If they do this and avoid any semblance of belittling the authority of the military medical officers, the latter will recognize in them most valuable auxiliaries and will welcome the relief which the Red Cross can bring to their wounded charges.

THE FIRST BATTLE AGAINST YELLOW FEVER.

The expected has happened, and yellow fever has attacked our troops in Santiago. The first reports that were permitted to reach the public were dated July 12th, on which day there were fourteen new cases. Within three or four days after that the total number of cases to date was admitted to have been upward of three hundred, so that it is certain that the disease has been among the troops for some time, probably having attacked them almost immediately after the landing was made. The policy of concealment was wholly justifiable at that time, for a confession of the truth would have served no purpose in protecting the home ports, and would simply have encouraged the Spaniards to delay surrender and would have caused unavailing anxiety and discouragement at home. All the accounts of the epidemic agree that the disease is in an unusually mild form, by far the greater number of those attacked recovering after the normal period of not very great suffering. Among the sufferers were very many of the Red Cross surgeons and nurses, all of whom, so far as is known, have entirely recovered or are convalescent. Many immune surgeons and nurses are on the way now to Santiago, and will be assigned to the fever hospitals immediately upon their arrival.

Now that there is no human enemy in our way, our sanitary officers in the conquered province have an excellent opportunity to give to the world an object lesson in cleanliness. And we are perfectly confident that, with the filth of Santiago destroyed, the houses cleaned and disinfected, the infected huts burned, and our camps removed to the hills as far as that may be possible, Gen. Vomito Negro will follow the lead of General Toral and yield to the inevitable. We have always believed that the chief reward to our country for undertaking this modern crusade against the Saracen, and one that will fully compensate us for expenditure of blood and money, will be the liberation of our Southern States from the constant menace of yellow fever. We are fighting not only for the freedom of Cuba from Spanish tyranny, but for the freedom of America from Spanish disease. The accomplishment of the first object is almost realized, and that of the second is plainly in sight.

It is not to be expected, however, that this glorious victory over disease can be won without a struggle, and we therefore welcome the battle which is now on, fearful indeed that the loss may be heavy, yet with no misgiving as to the outcome of the contest.

THE MODERN BULLET WOUNDS.

The study of the effects of the modern bullet wound has brought to light some interesting facts bearing more particularly on the relations of calibre to velocity of transit, in which the destructive tendency of the latter is markedly shown. Both the Spanish and the American armies are supplied with rifles of practically the same calibre and the comparison of results can be estimated only in connection with the rifle wounds made during our civil war by the Minié ball. In the small-bore arms the initial velocity is in a definite degree proportionate to the shortness of range, although not much essential difference is noted in results within a distance of five hundred yards. Obviously the direct penetrating power of these missiles is greatly increased, they scarcely ever lodging but almost invariably passing entirely through the body. The wound of entrance, in accordance with the ordinary rule, is small and cleanly cut, that of exit being large and ragged. The latter condition is shown in a very striking degree as to size and laceration on the side of the damaging effects of the small bullet. The

exits of the modern missiles are surprisingly large, due doubtless to the degree of resistance to the velocity. Consequently when bone is struck the comminution and laceration are correspondingly extensive and destructive. In brain wounds the skull is for similar reasons extensively shattered, the brain substance in the track being reduced to a pulp by the expansive force of transit. Judging from these facts, as verified on the field of Guantanamo by Assistant-Surgeon Van Duser, U. S. N., the only comparative safety was guaranteed by simple flesh wounds in which no considerable extent of tissue was involved. Fortunately there has been no opportunity for studying in our own sailors the wounds of larger dimensions caused by shells and flying splinters of wood and steel, but those from which the wounded sailors of Cervera's ships suffered are said to have been terrible.

A CASE FOR INVESTIGATION.

THE transport *Seneca* arrived at this port on July 20th, with nearly one hundred sick and wounded from Santiago on board, among whom were fourteen men with a suspicious fever. The ship was in a filthy condition, short of food and water, without any medical or surgical supplies or instruments, not even dressings for the wounds or a single clinical thermometer. In one case an abscess was opened with the blade of a jackknife, no scalpel being obtainable. When the captain was ordered to take the sick soldiers, he protested that there were no conveniences or even necessities for them on the ship, but his objections were overruled by some one at Siboney. Who that some one was is a proper subject for investigation by the military authorities, and when found his punishment should be such as to deter others in command from like brutality. The affair was a disgrace to the army and the country, and, as many foreign military attachés were on board the *Seneca*, our shame will be published to the world.

News of the Week.

The Losses at Santiago.—The final report on the casualties in the army before Santiago, from the first landing of the troops to the surrender of the city, shows a total of 1,914 officers and men killed, wounded, and missing. The killed number 246, of whom 21 were officers; wounded, 1,584, of whom 98 were officers; and missing, 84, of whom none were officers. Of the wounded only 68 have died. As we have before noted, the wounds made by the Mauser bullets were in general not of a serious nature, and the value of antisepsis in their treatment has been demonstrated in a way to convince the few though obstinate sceptics among the surgeons of the world. Notwithstanding the wretched physical condition to which most of our soldiers were reduced by the exposure to sun and rain in the trenches and by the lack of sufficient food, there were even in the field hospitals very few septic wounds, and among the entire 1,584 wounded there were but two cases of gangrene, of which one resulted fatally.

Red-Cross Aid Accepted by the Surgeon-General.—At a conference held in this city on Sunday afternoon between Surgeon-General Sternberg and members of the Red-Cross relief committee, the former said that he would accept very gratefully the offer of the committee to forward supplies for the sick and wounded at Santiago by the transport *Resolute* and the hospital ship *Missouri*.

A New Surgeon for the Sixty-Ninth.—Assistant Surgeon J. H. Oswell has been appointed surgeon of the sixty-ninth New York volunteers, vice Major Ramsay.

The State Hospitals for the Insane. — Assemblyman S. F. Nixon has recently presented a report to the comptroller of New York of an investigation made by him of the insane asylums under the care of the State. Mr. Nixon says that the management of the State hospitals, so far as the care of the patients is concerned, is satisfactory; but whether or not the financial condition of the State is such as to guarantee the extraordinary expenditures which are being made is a matter which, he says, would be well worth investigating. His strictures upon the Manhattan State Hospital are especially severe. The conditions which exist on the islands in the East River he characterizes as most deplorable, so far as the proper care of the insane is concerned. The buildings there, he says, were constructed for purposes entirely foreign to those for which they are being used at the present time. Mr. Nixon thinks that if it were possible to establish a colony more remote from the city of New York, where those of the patients can be employed who are able to render any service, it would be the most economical thing for the State to do. Dr. Wise, of the State commission in lunacy, commenting on this, is reported as saying that the per-capita cost of maintaining the insane previous to the passage of the "State-care" act was $216, and that now it has been reduced to $186. He thinks it would be calamitous to disturb a system for the care of twenty-two thousand of our most troublesome dependents, which is based upon such humane and economical principles as the system of State care at the present time. As regards the condition of the insane of New York City, Dr. Wise says that it has been marvellously improved under State supervision, although he is reported to have admitted that the buildings on the East River islands are not suitable to the purposes of a hospital.

Another Army Hospital Ship. — The steamship *Missouri*, one of the seven purchased by the government from the Atlantic Transport Line, which was the ship chartered by the government to send grain to Russia during the famine there a few years ago, has been selected as the new army hospital ship. The *Missouri* is due at Philadelphia from Liverpool on July 21st; discharging her cargo, she will come to New York to be refitted. Major William H. Arthur, surgeon, U. S. V., has been detailed as chief surgeon of the ship. The Daughters of the American Revolution will provide a steam launch to be used as an ambulance boat, and a library will be donated by members of the Stock Exchange in this city.

The Yellow Fever.—There is no cause for alarm in the report that yellow fever prevails among the troops in Cuba. There have been thus far about three hundred cases, but the disease is in an exceptionally benign form, the mortality thus far having been proportionately less than that from typhoid fever at Camp Alger and at Chickamauga. Now that the soldiers can be removed from the trenches, where they were often in water up to their hips and exposed in the intervals of rain to the vertical rays of the sun, and sent to camps on high ground, there is every reason to hope that the number of those attacked will grow less while the percentage of recoveries will increase. It is the announced intention of the military authorities to garrison Santiago with immune troops as soon as these can be sent from the camps where they have been waiting. The transport *Resolute*, carrying immune surgeons and nurses, and loaded with tons of supplies for the sick and wounded, sailed from this port on July 19th. The chief of the medical staff on the vessel is Dr. Thomas O. Summers, of St. Louis, now a surgeon of volunteers with the rank of major. Drs. Aristide Agramonte, and Fernandez de Ibarra, of this city, were among the number. The staff of nurses included seventy-three men and eight women, all of whom are immune and have had experience in the care of yellow-fever sufferers. The Red-Cross Society in New York, in answer to a request from Surgeon-General Sternberg, has been busily engaged in enlisting immune nurses, both men and women. All yellow-fever immunes who are willing to become nurses have been directed to make application at the Red-Cross Hospital, 233 West One Hundredth Street. A dispatch from Santiago announces that Dr. and Mrs. Lesser and four of the Red Cross have been down with yellow fever, but are now convalescent. The transport *Seneca*, with ninety-nine sick and wounded from Siboney, arrived at Old Point Comfort on July 18th, but as there were three cases of yellow fever aboard the vessel was immediately ordered to this port, and the sick and wounded were taken to the quarantine hospitals for treatment. Dr. Doty, health officer of the port, has made the suggestion that all those ill with yellow fever be brought directly here, where the facilities for isolation are complete. It is certain that none of the sick and wounded will be landed at any ports south of New York and they may be taken still farther north. There is a naval fever hospital at Widow's Island, off the coast of Maine, which is supplied with everything needful for the treatment of yellow fever. Recently all the buildings have had an overhauling, new supplies have been sent there, and surgeons immune from the fever have been detailed to report there whenever needed. It is not believed that any cases of yellow fever will develop on the fleet, but it is quite probable that, since the army has no such station, the facilities of Widow's Island will be offered to the war department, should the necessity arise of sending a large number of yellow-fever suspects to the North. There is no yellow fever in Florida, either at Tampa or at Key West, and it is improbable that any cases of the disease will occur there so long as the Havana blockade continues and the troops from southern Cuba are brought directly here. Some malicious person started a rumor that yellow fever existed at Tampa, and now the State authorities are hunting for him. If caught he will be punished under the present laws by a fine of $1,000 or imprisonment for six months.

The Late Dr. Joseph O'Dwyer.—At the meeting of the section on diseases of children of the American Medical Association, held at Denver in June, it was moved and carried unanimously that "a memorial committee" be appointed to commemorate the late Dr. Joseph O'Dwyer. This committee was authorized to collect money, and to act with other bodies for the same purpose. The committee is composed of Drs. Louis Fischer, New York, chairman; J. P. Cozer Griffith, Philadelphia; F. X. Waxham, Denver.

What Became of the Red-Cross Supplies.—*La Region*, a newspaper published at Matanzas, says that all the bread made at the bakehouses there is "improved" with the flour brought to Matanzas for the reconcentrados, which shows that the latter never got it. The flour was sold to the bakers by the Spanish officials after the Americans left the place in April.

Ptomain Poisoning.—Over one hundred persons who had attended a lodge meeting at Summit, N. J., on the evening of July 14th were seized during the night with symptoms of ptomain poisoning. The cases were all mild and none of the sufferers died. The poison was supposed to have been distributed in some potted ham eaten in sandwiches. At Camp Alger on July 19th, fifty-five men were suddenly taken ill with symptoms of poisoning. The trouble was traced to hash which the men had eaten at breakfast, which was probably made of meat which had become tainted.

Medical Examinations to be More Strict.—Considerable complaint was made at the beginning of the war of the alleged unnecessary severity of the medical examination of the volunteers, many of them who were members of the national guard and seemingly in good condition having been rejected. It appears, however, that the examinations, instead of being too severe were in many cases not severe enough, for a general order has just been issued from the adjutant-general's office requiring closer attention in future to the physical condition of men examined and accepted for service.

Typhoid Fever at the Camps.—Fifty cases of typhoid fever have been reported at Camp Alger, and with the purpose of stopping the epidemic the troops are being moved to Dunn Loring, three miles away, where the water supply is better. At Chickamauga there were eighty cases among the fifty thousand troops, chiefly raw recruits.

Dr. R. O. Moffat, a young physician of Toronto, died in a dentist's chair on Monday. He took chloroform to have six molar teeth extracted, and died while the operation was in progress. All the teeth had not been extracted when he began to recover from the effects of the anæsthetic, and more was given him, when he died.

Obituary Notes.— Dr. John Hewitt Wilson, of this city, died suddenly of heart disease on July 17th. He was born in 1819, and was graduated in medicine from the University of Glasgow in 1844. Soon after graduation he came to this country and practised here up to the time of his death.—Dr. William H. Hodgman, of Saratoga Springs, N. Y., died of chronic nephritis on July 15th, at the age of forty-seven years. He was a graduate of the College of Physicians and Surgeons, New York, in 1873. He was for some time health officer of the village.—Dr. Alan Penneman Smith, of Baltimore, died at his home in that city on July 18th. He was born in Baltimore in 1840, and was a son of the late Dr. Nathan R. Smith. He was a graduate in arts of Princeton, and received his medical degree from the medical department of the University of Maryland in 1861. Dr. Smith was one of the original trustees of the Johns Hopkins University, and was connected with nearly every hospital and medical institution in Baltimore. He is survived by six children, one of whom is a medical practitioner. Dr. Smith had a wide reputation as a skilful and successful lithotomist at a time when that operation was more frequently performed than it is at the present day.

Only Trained Nurses Wanted.—So many applications have been received from women who have had little or no experience in nursing, that the officials of the Red Cross Society in New York have issued a notice that only professional nurses in sound health are wanted or can be accepted. The service required is of the most exacting kind, and consequently a good physique is as necessary as are professional training and experience.

The Non-Combatants.—In a recent issue the *Evening Post* says: "We may soon be hearing more of the services of forgotten heroes at Santiago—the army surgeons. With hostilities at an end, more attention will be given to the work done in hospitals; but the heroic qualities of the medical staff have been displayed on the field as conspicuously as those of the men in the fighting-line. Under fire, without the moral support of being one of the combatants, their courage and self-devotion are fully as great as can be found in the front ranks. Surgeon Church exposed himself as freely as any of the Rough Riders, and his work of relief was as gallant as their charge." And we may add that Surgeon Gibbs was the first commissioned officer of the United States forces to fall on Cuban soil.

A New Bullet for the Indian Army.—A description of the new service bullet which has been invented to supersede the Dum-dum bullet was published in the *Times* of June 28th. The Dum-dum bullet was introduced in India for the purpose of stopping the rush of fanatics ("ghasi"). It is a solid bullet of hardened lead enveloped in nickel, all but the point, which was left bare, so that on impact the bullet "set up," or expanded, inflicting much more severe wounds than the fully enveloped bullet, which in most cases passed through the body unaltered, much as if it were a bolt of steel. It is stated that the new service bullet is of the same diameter (0.303), the same length (1⅝ in.), and the same weight (215 gr.) as the Lee-Metford. "The case is of nickel, the base only being left empty" (*sic*)—it is evident here that "case" means the "envelope" of the bullet, not the cartridge case. The conical end is left empty, and when it strikes a man burrs, opens backward, and lodges in the body, penetration being lessened and shock increased. We have not seen the bullet in question, and are dependent on the *Times* report; but as we read it the new bullet seems in some ways to resemble the later-pattern Snider bullet, in which there was a cavity in the conical apex, which, containing air compressed on impact, burst open violently and inflicted most severe wounds. In the bullet it would appear that the cavity will be formed by the nickel envelope being left empty in the nose or apex, and on impact the compressed air will act as an explosive, burst and burr the envelope, which, spreading open, will present a large striking-surface, and cause immense injuries to trunk and limbs. It would be interesting to know if any experiments with this new bullet have been made on the bodies of animals in the presence of military surgeons, and, if so, what their report has been. Professor v. Bruns made some incisive remarks on the Dum-dum bullet, going so far as to call it an inhumane projectile; but if the new service bullet acts as it is reported to do, probably some stronger language will result.—*British Medical Journal.*

A Tropical Hospital.—A writer in the *Hospital* mentions a novel feature of the new general hospital for Europeans in Calcutta, India, the cornerstone of which was recently laid, which consists in a system of ventilation during the hot and rainy seasons by cold and dried air. During the hot and rainy seasons Calcutta has a temperature ranging from 85° to 95° F., and a humidity which frequently reaches 90 per cent. It is proposed to establish a uniform temperature in the wards, of from 75° to 80° F., and a humidity reduced to about 60 per cent., as a necessary part of the process of cooling the air.

Saco Pool.—Dr. Frederic Bacon, of Omaha, writes concerning Saco Pool, recently mentioned among the health resorts of Maine, that there is no such resort. The Pool, he says, is a peninsula adjacent and connected to Biddeford, which lies across the river from Saco, and it is, therefore known as Biddeford Pool, although situated nine miles from the city proper. The Pool has no shade trees, but makes a pleasant resort for one desiring complete rest from the noise and bustle of city life.

The Section on Tropical Diseases.—The programme of the new section on tropical diseases at the approaching meeting of the British Medical Association in Edinburgh has been published. Set discussions will be had on the following subjects: 1. "The Unclassified Fevers of the Tropics," to be opened by Brigade-Surgeon-Lieutenant-Colonel Crombie: 2. "Beriberi in Temperate Climates," to be opened by Dr. Conolly Norman, Dublin; 3. "The Epidemic of Plague in India," to be opened by Dr. W. J. R. Simp-

son, late of Calcutta. The following papers will be read: "Sketch of Disease at Hong-Kong in 1865 among the Troops, with Views, Charts, etc.," by Surgeon-Major Black; "Abdominal Surgery in the Tropics," by Surg.-Capt. E. Harold Brown; "Surgical Requirements of the Tropics," by Mr. James Cantlie; "The Malarial Problem in its Epidemiological Aspects," by Dr. Andrew Davidson; "Plague in India," by Prof. W. M. Haffkine; "Enteric Fever in Armies and Tropical Climates," by Surg.-Maj.-Gen. J. B. Hamilton; "Training of Regimental Officers in the Prevention of Disease in the Army in Tropical Climates," by Surg.-Capt. Louis Hughes; "Appearance of Pigmentation in Lymphocytes in Relation to the Diagnosis of Malaria," by Dr. Patrick Manson; "(1) Pellagra; (2) The Treatment of Acute Dysentery," by Dr. Sandwith, of Cairo; "Clinical Aspects and Treatment of Malarial Fever," by Surg.-Maj. Tull Walsh; "Malarial Eye Affections," by Surgeon-Major Yarr. The officers of the section will be: *President*, Dr. Patrick Manson; *Vice-Presidents*, Drs. Andrew Davidson, Andrew Smart, and William John Ritchie Simpson; *Honorary Secretaries*, Mr. James Cantlie and Surg.-Capt. M. Louis Hughes.

The Offer of the Health Board.—The president of the New York board of health has written to Surgeon-General Sternberg, offering the services of the physicians in the health department to take care of the sick and wounded soldiers brought to this port.

Abdominal Bands for Soldiers in the Tropics.—The question as to whether the wearing of a flannel band over the abdomen affords any protection against diarrhœal disease in the tropics is about to be answered officially by a board of army surgeons in Washington. A large number of charitable persons and organizations all over the country (the picking of lint, which was their occupation during the civil war, being done away with) have begun the manufacture of the so-called cholera bands for the use of the soldiers, and the attention of the medical department of the army has been called to the matter. The result was the detail of the board, to be presided over by Surgeon Dallas Bache.

In France, at the coming "world's fair," there will be a department devoted to progress in medical and allied sciences. This country has much to be proud of in these branches, and steps should be taken early to secure fair representation.

The Degree of M.D. in Prussia.—The Prussian minister of education has decided that an M.D. degree will hereafter be conferred by the universities of that country only upon candidates who have passed the State examination prescribed by the laws of the German empire. The academical degree will now be tantamount to a license to practise. Under the former anomalous conditions a doctor of medicine who had not passed the State examination might render himself liable to prosecution by putting his title on the street door or the wall of his house (thereby misleading the public), although he was at perfect liberty to attach it to his name on the doorplate of his private apartments.

An Accident to the Prince of Wales.—On Sunday last the Prince of Wales fell on the stairs at a country house where he was visiting, and fractured his patella. On Monday, while he was being carried to the railway station in a chair, the latter broke and let its occupant fall. No new injury was sustained, but the prince received a very unpleasant shaking of his broken kneecap. As he has the misfortune to be an exalted personage, his surgeons will probably fear to treat his injury radically, with the result that the poor man will be lame for life.

Major Ogden Rafferty, a brigade surgeon in the army, well known in New York, where he made his medical studies, has been ordered to report in person to the surgeon-general.

The Prize of the South Carolina Examining Board.—A prize of $50 was offered by the medical examining board of South Carolina for the "best general average" at the State examination, held May 16th, 17th, and 18th. The fortunate winner was Dr. R. E. Hughes, of Laurens, S. C., formerly of Virginia.

The German Emperor's Donation to the Red Cross.—Emperor William has donated 10,000 marks to the Red Cross Society for the benefit of wounded Spanish and American soldiers.

Civil-Service Examination for a Diagnostician.—Notice is given by the municipal civil-service commission, of the city of New York, that a competitive examination for the position of diagnostician will be held at the office of the commission, in the new criminal court building, Centre, Elm, Franklin, and White streets, on Tuesday, July 26th, at 10 A.M. The subjects of examination will be technical knowledge and experience. Persons desiring to make application or seeking for further information may address the secretary of the commission, Mr. Lee Phillips, at the address above given.

Malarial News.—Blackwater fever is not malarial, according to Koch, but is rather an expression of poisoning by quinine. The same learned bacteriologist and therapeutist has arrived at the conclusion that persons who have suffered from an attack of malarial fever and have recovered therefrom without the aid of quinine have acquired immunity. The native Africans, he says further, never have malaria, and their exemption is due to hereditary immunity.

A Hospital Service in Alaska.—It is proposed to erect and maintain a chain of hospitals extending from Seattle to Circle City in Alaska. One building has already been erected in Skaguay, and contracts have been let for others at Victoria and Juneau. Other places selected are Lake Bennett, White Horse Rapids, Stewart River, Dawson City, and Circle City, and the service will be further extended as gold discoveries lead to the creation of new settlements. The support of the hospitals is to be secured by an annual subscription of $12 from miners and others going to the Klondyke. About ten per cent. of those treated up to the present have been charity patients.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 2, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

The Successful Treatment of Hæmophilia by the Injection of Serum.—DR. ALBERT FRY, of Newark, N. J., read this paper. Hæmophilia, or bleeder disease, he said, was exclusively a hereditary tendency to hemorrhages, with healthy integument, and abundant and marked extravasations of blood following the slightest injury. The hemorrhages were accompanied by swelling of the joints, resembling rheumatic arthritis, which was due to the extravasation of blood into the joint. Anæmia was a marked feature of this disease. Little or nothing was known about the pathology of hæmophilia. It had been claimed that the cause of the bleeding was a malformation of the blood-vessels, or a deficiency in one or the other tissues making up the same; that it was due to a deficiency of the fibrin-forming elements, or to a combination of these causes. Virchow ascribed the cause to the lumina of the blood-vessels, claiming that they were too small for the amount of blood circulating through them, and that with increased tension a rupture of the fine walls occurred. As to etiology, the speaker claimed that the most marked feature of this disease was its hereditary tendency. Another feature was the fact that it was more frequent among the male than among the female members of a hæmophilic family. Men coming from a bleeder family did not, as a rule, generate bleeder children, though they might themselves be or not be bleeders. Mothers, the daughters of a bleeder family, though themselves free from hæmophilia, might give birth to hæmophilic children. The tendency to bleeding seemed to be derived from the female only. The diagnosis was not very difficult, inasmuch as the uncontrollable hemorrhages revealed the state of affairs. Treatment was very unsatisfactory, if followed out according to the materia medica of older days. Heredity was a very strong indication for the prophylactic treatment. Grandidier had laid down the following rules for the prevention of the spread of the disease: (1) All females coming from a bleeder family, whether themselves free from the disease or not, should not marry. (2) All males who were not themselves bleeders should be allowed to marry. (3) Male members of a bleeder family, of which it had been proven that other male members had generated bleeders with daughters of families not so affected, should not be allowed to marry. According to the speaker, individual prophylaxis was of the utmost importance, and should be conscientiously carried out from infancy. All such operations as severing the lingual frænum, circumcision, removal of nævi, piercing the ears in female children, extracting teeth, etc., should not be resorted to at all, or only with the utmost caution. Vaccination had not been shown to cause trouble and might be resorted to with impunity. Leeches and wet-cups must be avoided. Great care must be exercised when the children commenced to walk, inasmuch as the most insignificant injury caused by falling might give rise to enormous joint swellings. When the children grew older, calisthenics, gymnastics, and rough play should be strictly avoided. At maturity, when the question of a livelihood would arise, only occupations of a more or less sedentary nature should be chosen. The general treatment was more or less on the tonic order. Inasmuch as the bleeders were anæmic, the mineral and vegetable tonics might be used. All food which had a tendency to irritate and to cause congestion should be avoided; also the stronger alcoholic beverages. Milk, lemonade, and cooling drinks were advisable, as was also frequent change of climate. As regards drugs, the prolonged use of chloride of iron had been highly recommended. Dr. Fry said he had given this remedy a thorough trial in one of his cases, and instead of benefiting the trouble it seemed to aggravate it. Others had advised the mineral acids, sugar of lead, acetate of lead, sulphate of magnesium, Glauber's salts, etc. The two latter remedies seemed simply to flush out the bowels and thus removed all tendency to congestion. The actual hemorrhages had been treated with ergot, hydrastis, acetate of lead, opiates, argentum, styptics, turpentine, tannic acid—in fact, almost every drug in the pharmacopœia, but without avail. As a rule, the bleeding continued until a stage of syncope was reached, which seemed to be in these cases nature's own method of checking the hemorrhage. The mechanical treatment consisted in affording absolute rest to the joints by plaster-of-Paris bandages, and by compression of the main arteries to prevent bleeding from their respective branches. The latter expedient had always been followed by sloughing of the injured parts. Ice had proved favorable, inasmuch as it relieved the pain and congestion. Regarding serum therapy, Dr. Fry said that in January, 1898, his attention was called to an article by Drs. Feltz and Pigot (*Gazette Hebdomadaire*, No. 83, 1897), who had obtained excellent results in a very severe case of purpura by injections of artificial serum. After the first injection of two hundred and fifty cubic centimetres the general condition of the patient became better and after two more injections the symptoms of purpura disappeared entirely. These authors had suggested the same treatment in hæmophilia. Dr. Fry said he had thus far treated three cases of hæmophilia by injections of horse serum, with very satisfactory results, although he still looked upon the method as an experiment. His patients were three brothers, members of a family of eight boys, five of whom were bleeders. About two years ago one of the bleeders fell and fractured his thigh, and died one week later from intramuscular and osseous hemorrhage. A second brother, also a bleeder, developed appendicitis last fall, from which he recovered, but which was shortly afterward followed by intestinal hemorrhage and death. In the three remaining bleeders in the family the serum treatment had been employed by Dr. Fry. The first was J. M——, aged seventeen years. This patient, up to the time this treatment was commenced, had constantly suffered from ecchymoses, swollen joints, and actual hemorrhages. In March of this year he was suffering from a severe swelling of the elbow-joint, and on March 17th the first injection of the serum was made, the quantity being twenty cubic centimetres. The site of the injection was the muscular tissue of the posterior part of the thorax, just below the inferior angle of the scapula. The puncture produced well-marked bleeding, which was controlled by dressing with a Bernay's sponge. On the following day there were well-marked pain and swelling at the site of the injection, which gradually disappeared. The swelling in the elbow-joint was less marked and less painful. After a second injection on March 20th, the elbow-joint became normal; there was no bleeding at the point of puncture on this occasion. Up to the present time this patient had received three hundred cubic centimetres of the serum; his joint troubles had entirely disappeared, he felt well, and recently, when he accidentally cut his finger, the bleeding was slight. During the course of this treatment the patient's urine was frequently examined, with negative results. Practically, no constitutional symptoms followed the injections. In the second case reported by Dr. Fry, in which the principal lesions were confined

to the joints, two hundred cubic centimetres of serum had been injected up to the present time. The first injection was made on April 3, 1898, and was followed by a rapid improvement in all the symptoms. The only complication in this case was a severe generalized urticaria, which appeared two days after the first injection. In the third case the patient was a young man, twenty-three years old, who suffered from periodical meningeal hemorrhages, giving rise to severe headache and a state of acute dementia. In this case only ninety cubic centimetres of the serum had been used up to the present time, as each injection had given rise to high fever and marked urticaria. His periodical attacks of headache, however, had decreased in severity and his mental condition was clearer. The following conclusions were drawn by the author: (1) That hæmophilia was a disease due not simply to a malformation of the blood-vessels, but also to a certain malcondition of the blood, marked by a deficiency of one or more of its fibrino-plastic elements. (2) If due to a deficiency of these elements, and amenable to treatment with a serum so poor in these elements as that of the horse, more gratifying results could probably be achieved with a serum derived from animals whose blood was richer in those elements.

Dr. B. Farquhar Curtis said he knew of no condition that the surgeon had to meet which was harder to overcome than this tendency to bleed which was observed in hæmophilia. The ordinary methods for arresting hemorrhage proved of no avail. He hoped that something practical would come out of the method suggested by Dr. Fry, and promised to give it a trial the next time an opportunity offered itself.

Dr. H. D. Chapin said that, as all drug methods had proved unavailing in the treatment of hæmophilia, he thought the medical profession was indebted to Dr. Fry for his suggestion to try injections of blood serum. The possible danger of injuring the kidneys by this method of treatment, however, should be borne in mind. The speaker said that some time ago he had made a series of experiments in this connection, injecting into a number of dogs and guinea-pigs from twenty to thirty cubic centimetres of blood-serum every day for ten days; all of them developed cloudy swelling of the kidneys. In another series of cases, in which the injections were made less frequently, the cloudy swelling did not appear. Another point was whether the improvement in Dr. Fry's cases was permanent or only temporary. The cases had not been under observation long enough to prove that the hæmophilia was completely controlled. If these patients after two or three years still showed this improvement, then the serum treatment was certainly a great triumph. It was known that a certain number of cases of hæmophilia improved with age, the tendency of the blood to clotting increasing.

Dr. Mary Putnam Jacobi said that hæmophilia implied a congenital deficiency in the elaboration of the blood and the blood-vessels. Spontaneous rupture of the blood-vessels, without any lesion of the surface, occurred so frequently in these cases that the trouble was undoubtedly not confined to the composition of the blood. Women were more exempt from this disease than men, the proportion being one to twelve, and the fact had frequently been noted that a hæmophilic woman during confinement was not especially liable to suffer from excessive hemorrhage. This was interesting, as the bleeding from the uterus was expected to be controlled by contraction of the muscular tissues and not by contraction of the blood-vessels themselves. Dr. Jacobi then referred to the experiments of Arthus, Pikelharing, and Bendict in connection with the subject of the relation of the lime salts to the coagulation of the blood. The latter writer had made the assertion many years ago that there was no cell formation without lime, and it might now be said that there was no fibrin molecule which did not contain an atom of lime. It had been shown that injections of peptone into animals would entirely destroy the coagulability of the blood, besides paralyzing the heart and greatly lowering the blood pressure; but by the addition of lime to the peptone before it was injected its toxic power was entirely destroyed. Wright, of London, had made some experiments with chlorate of calcium in cases of hæmophilia, and had reported two instances in which the administration of this drug arrested prolonged hemorrhage. The direct injection of blood serum into the tissues had considerable advantage over the above methods of treatment, because the serum contained lime in its organic combination. Dr. Fry, in his paper, had made the statement that hæmophilics were anæmic. Dr. Jacobi said that, on the contrary, many authorities, among them Virchow, held that the condition of the blood was rather that of plethora than anæmia, and that there was an overabundance of blood corpuscles.

The President, Dr. Janeway, said that the following case, which he recently saw in consultation, might be of interest in connection with this subject. The patient was a young man, aged twenty-five years, who, while walking across the floor, suddenly became paralyzed from the waist down. A myelitis was at first suspected, but on examining the patient the speaker found the limbs stiffened out in a manner which suggested spinal hemorrhage. The paralysis gradually extended and the patient died in two weeks. The autopsy showed a hemorrhage within the subarachnoid space, which had broken through and filled the entire cervical canal. The case was interesting, as it explained a sudden paralysis in a person with a hemorrhagic tendency. It was learned that the boy's brother had lost an eye as the result of a retinal hemorrhage, and the boy himself had always bled freely after even the slightest cut. It was on this account that an operation was not deemed advisable.

Dr. Fry, in closing, said that in his cases the urine had been examined after each injection of the serum, and was always found free from albumin. As regarded the treatment of hæmophilia with lime salts, he said that one of his cases had been treated with various preparations of lime for two years, and the patient died from an intestinal hemorrhage. The speaker said he did not claim that the hæmophilia was solely the result of a lack of the fibrin-forming elements of the blood; it was also due to a defect or malformation of the blood-vessels. As regarded the permanence of the result in his cases, he did not care to venture an opinion at present.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 11, 1898.

T. Mitchell Prudden, M.D., President.

Case of Acute Yellow Atrophy of the Liver.—Dr. F. C. Wood presented a specimen of acute yellow atrophy of the liver, taken from a woman, thirty years of age, who had been operated upon for a uterine fibroid. At the time of the operation it was found that there was a large pyosalpinx on the left side. For about three days the case did well; then it was noticed that the conjunctivæ were very yellow. On the fourth day muscular twitchings developed, limited to the hands and feet. The following day she was comatose, and death occurred twenty-four hours later. During the last two days the jaundice was very marked. At the autopsy the liver and kidneys presented the chief points of interest. The liver was extremely soft so that it did not retain its shape when removed from

the body. On section, it presented a dead yellow hue. There was no obstruction to the flow of bile, and no lesions were discovered in the intestinal tract. The kidneys were very pale, the markings were lost, and the organ was deeply tinged with yellow. Microscopical examination of the liver showed complete degeneration of the liver cells, and a great deal of fat in the cells. The kidneys showed the lesions of acute degeneration. The tubular epithelium was swollen and did not stain. Cultures taken from the liver gave streptococci in one tube, but further investigation seemed to show that this was a contamination. As the woman had been well before operation, and there was a likelihood of infection having taken place from the pyosalpinx during operation, it seemed probable that such an infection was the underlying cause of the condition found at the autopsy. A section of the liver was exhibited under the microscope.

Dr. Eugene Hodenpyl said that Ziegler stated in his text-book that the lesions of acute yellow atrophy of the liver usually began around the periphery of the lobule, and extended toward the centre. In a specimen at the laboratory of the College of Physicians this condition was reversed. From an examination of the sections from the case just presented it seemed probable that the process had from the onset involved the parenchyma of the lobules uniformly.

Case of Suppurative (Streptococcus) Portal Phlebitis, with Rupture and Fatal Peritoneal Hemorrhage.—Dr. Eugene Hodenpyl presented specimens from such a case. The patient was a young man who had been sick for less than three days with symptoms of a mild and indefinite character. Death took place quite suddenly from a large peritoneal hemorrhage. He was twenty-five years of age, temperate in his habits, and had enjoyed good health previously, with the exception of an attack of typhoid fever three years before. His last illness began with a chill, followed by general pains throughout the body associated with an occasional attack of vomiting. The next day there was some little pain all over the abdomen. On his admission to hospital his temperature was 98° F.; pulse, 66; respirations, 24. The examination of the urine was negative. There were no abdominal tenderness and no tumor. The chief complaint was of abdominal pain and prostration. The diagnosis was neurasthenia. Ten hours later he suddenly collapsed; there was "air hunger," and death occurred without further premonitory symptoms. At the autopsy the abdominal cavity was found distended with clotted and fluid blood, and the organs were quite pale. On the under surface of the liver in the transverse fissure was a small sac, and on one side of the sac was an irregular opening. From its position the sac was regarded as a dilated portal sinus which had ruptured. The liver was pale, but no lesions were detected on macroscopical examination. Unfortunately no cultures were made from the various organs. On microscopical examination it was found that the sac was actually the wall of the portal vein, and that this wall was extensively infiltrated with leucocytes and fibrins, and that there were numerous streptococci present. Sections through various portions of the liver revealed a suppurative portal phlebitis throughout the entire organ, associated with the presence of streptococci. No gross lesions of the intestinal tract were discovered.

Rupture of an Abdominal Aortic Aneurism Simulating Tumor of the Kidney.—Dr. Hodenpyl also presented a specimen of false aneurism which had ruptured into the retroperitoneal tissue, forming a mass which simulated a tumor of the kidney. The specimen was taken from an old syphilitic who for one year previous to death had had a dull constant pain in the epigastrium, with occasional attacks of vomiting. Four days before death almost complete suppression of urine suddenly developed, associated with very marked prostration and pallor. He was admitted to hospital because of the urinary symptoms. Physical examination showed a large mass in the left side, in the region of the kidney. Suspecting a tumor of the kidney, Dr. A. B. Johnson performed an exploratory laparotomy on the left side, and opened up an enormous blood sac, from which the hemorrhage was most profuse. The patient died shortly afterward. The autopsy showed in the thoracic portion of the aorta a small aneurism, and in the abdominal aorta, near the site of the cœliac axis, a large pouch was found lying on the anterior surface of the aorta and communicating with a small sacculated aneurism. On the left of the false aneurism was a ragged perforation. A large quantity of effused blood was found behind the peritoneum.

Dr. Henry Power said that the first case reminded him of an autopsy made by Dr. Hodenpyl some time ago upon a woman who had died of rupture of the bladder. In the veins of the spinal cord there had been found an infiltration of round cells, apparently without any cause. No bacteria were present. Possibly the greater distance from the intestinal canal might explain this fact. A careful study of the literature at the time brought out an exact description and accurate drawings of the existing condition, in Ziegler's "Pathology," under the head of "Syphilitic Changes."

Fatal Case of Anthrax.—Dr. Charles Norris presented specimens from a case of anthrax, occurring in a longshoreman who had come to the Vanderbilt Clinic on April 5th. The man said that he had been in the habit of handling hides, and had last done this seven days previously. On April 1st, he noticed a small pimple over the left side of the jaw, but he felt well until four or five hours become coming to the hospital; at that time there had rapidly developed œdema of the face and neck, associated with malaise and fever. Examination showed a slightly depressed pustule, about the size of a five-cent piece; the epithelium around the edge was elevated by an accumulation of clear, colorless serum containing anthrax bacilli in vast numbers. A mouse inoculated with one loop of an agar culture died in eighteen hours. The pulse was rapid, intermittent, and small. On April 6th, the pustule was excised, and a long incision was made along the neck down to the clavicle, to relieve the œdema. On examination of the blood it was found to be sterile. The man died three days after the onset of the œdema. The chief clinical symptoms were the œdema and the great prostration. The autopsy was made by Dr. Hodenpyl seventeen hours after death. The subcutaneous tissues of the neck, thorax, and abdominal wall, and the tissues of the mediastinum, were swollen and very œdematous. The peritoneal cavity contained some turbid fluid. In places, the small intestine was the seat of an extensive hemorrhagic infiltration. The mesentery of the small intestine and the retroperitoneal cellular tissue were the seat of extensive interstitial hemorrhage. The liver was normal in size and in appearance on section. The spleen was enlarged, soft, and congested. The kidneys appeared to be normal. In the sections of the pustule numerous bacilli were seen, occupying the rete mucosum in clumps. Sections of the liver showed areas of degeneration which appeared to be toxic in their origin, as no bacilli could be found in the sections or by culture. The kidney showed only a slight parenchymatous degeneration. Cultures were made at the autopsy, and anthrax bacilli were recovered from the spleen and blood, but not from the liver. From the liver, spleen, and blood numerous colonies of the Friedlander bacillus were recovered. Microscopical specimens from this case were also exhibited.

Dr. W. H. Park said that he was reminded of a case sent about a year and a half ago to the health-department laboratory. Dr. Nammack had excised a large piece from the neighborhood of the eye, yet examination showed only five colonies of anthrax on two plates, and none was found in cultures in broth tubes. This fact illustrated the ease with which the condition might be overlooked. This patient recovered.

Dr. Norris said that he understood it was often difficult in cases which did not terminate fatally to recover the anthrax bacilli from the pustule. About twenty-five per cent. of the cases were fatal when the pustule was on the face, and about five per cent. when the pustule was on the lower extremity.

Demonstration of the Yellow-Fever Bacillus (Sanarelli).—Dr. Charles B. Fitzpatrick said that Sternberg in his recent papers seemed to be of the opinion that Sanarelli's bacillus was identical with his bacillus X. Dr. Fitzpatrick believed that there were well-marked differences between the two bacilli. Sanarelli gave as the diagnostic point of his bacillus its appearance on agar—a concentric growth having an irregular outline. The central part of the colony was dark and was surrounded by a more transparent zone of growth. A specimen was exhibited which was the counterpart of one received from Sanarelli. Sanarelli's bacillus lost very rapidly its characteristic form of growth. Dr. Fitzpatrick said he thought it would be found in time that the bacilli which had been described by Sternberg, Sanarelli, and himself belonged to the colon group. Dr. Sternberg stated in his work on the etiology of yellow fever that his bacillus X was the bacillus coli communis, and was, therefore, not the cause of yellow fever. Dr. Fitzpatrick said that the bacilli (bacillus coli icteroides and bacillus coli concentricus) which he had described in the Medical Record of January 29, 1898, he now believed to be a single, separate, special form of the colon group, and would designate it as the bacillus coli icteroides. Its special virulence and other characteristics were sufficient to separate it from the ordinary colon bacillus. This bacillus (bacillus coli icteroides), when grown at 37° C. for about sixteen hours and then kept at room temperature for twenty-four hours, forms on agar either ordinary round colonies, about one millimetre in diameter, with a dark central point, or concentric colonies, about three to five millimetres in diameter, with a dark, round, central area surrounded by a transparent zone, with a somewhat raised and irregularly round border. It differed from the bacilli icteroides (Sanarelli) in having, when grown in bouillon, a distinct flaky surface growth and a well-marked deposit. Dr. Fitzpatrick believed that the bacillus coli icteroides could very well be the agent of infection and death in yellow fever, notwithstanding that it belonged to the colon group of bacteria.

Melano-Sarcoma of the Vagina.—Dr. F. S. Matthews reported a case. Next to the Fallopian tube no part of the female genital tract, he said, was so infrequently the seat of primary sarcoma as the vagina. Of the primary sarcomas of the vulva a large per cent. were melanotic. In this they differed from those of the vagina. A search through the literature of the subject had revealed only one undoubted case. This was reported by Parona (*Ann. univ. med. Chir.*, Milan, 1887, page 241). Veit ("Handbuch für Gynäkologie," 1897) in his article on tumors of the vagina had said this was the only reported case of melano-sarcoma primary in the vagina. He spoke of it as a "melanotisches Spindelzellen Sarcoma in Septum vesico-vaginale." In the preparation of this article Veit had collected forty-seven cases—seventeen in children and thirty in adults—the case of Parona being among the latter. Several cases of sarcoma of the vagina had been reported since the appearance of Veit's article. Two of these were reported by V. Horn (*Monatschrift f. Geb. u. Gyn.*, iv., 1896, page 409). Though they were not melano-sarcomas, one of them deserved mention in this connection. The patient was a resident of Hamburg, aged forty-nine years, married. She had had seven children and five abortions. The last child was ten years of age. She had reached the menopause five years previously. At time of operation she had been troubled for five months with a foul-smelling bloody vaginal discharge. She was operated upon twice. At the first operation the primary tumor in the vagina and also sarcomatous inguinal glands were removed. The tumor returned speedily in the vagina, at the orifice of the urethra, in the labia, and in the inguinal glands. The primary tumor was an alveolar spindle-celled sarcoma free from pigment, but the uninvolved mucous membrane was pigmented, the pigment being chiefly confined to the corium. The interesting feature, however, was that the secondary deposits, both those removed at the primary operation and later, were deeply pigmented. Horn stated that this was not to be considered as melanotic sarcoma. The presence of pigment in the secondary deposits, he said, was due to the hemorrhagic character of the growth, the blood pigment being taken up by the cells of the new growth. The speaker said that this left the case of Parona's as the only one reported of primary melano-sarcoma of the vagina. To this the report of a case occurring in the service of Dr. George M. Tuttle at Roosevelt Hospital might be added. The tumor came into the speaker's hands through the kindness of Dr. Eugene Hodenpyl, the pathologist to the hospital.

A. K——, aged forty-two years, married, housewife, Russian. Admitted to hospital, November 20, 1897; discharged, December 3, 1897. Menopause eleven months ago. Seven children, the last ten years ago; no miscarriages. The history of the present illness was that for two months she had had a feeling of lack of support and falling of the uterus, and recently had felt something in the vagina. She had also had a slight dragging pain. The discharge had not been profuse but was increasing.

On physical examination the uterus and appendages were apparently normal. There was a tumor growing from the anterior vaginal wall. It began an inch behind the meatus urinarius and extended backward to within an inch of the cervix uteri. The growth measured an inch in its lateral diameter. It was of the size of a hen's egg, had a rough, cauliflower-like appearance, bled easily, was hard, and very dark colored. The growth was removed with knife and cautery. There was very little bleeding. The vagina was packed with iodoform gauze. The patient left the hospital improved but a large granulating area persisted over the anterior vaginal wall. The tumor, when removed, was oval, of about the size of a hen's egg. In its thickest portion it was twenty to thirty millimetres thick and was thrown into irregular elevations. Microscopically, it was a large round-celled melano-sarcoma. It lay upon the muscular wall of the vagina but had not invaded it. In the central portion of the tumor it was superficial and presented a ragged surface denuded of epithelium; laterally it was covered by the vaginal mucous membrane. The tumor became thinner toward its lateral portions and appeared at the periphery as a growth not more than one millimetre in thickness, dissecting its way immediately under the mucous membrane and sending prolongations up into the papillæ. The pigment showed no definite arrangement. Those cells which contained it were filled with it so as to be perfectly opaque. The number of pigment cells in different portions of the tumor was variable. No part of the tumor was entirely free from pigment. At the advancing edge the cells were pigmented, just as in the central portions

of the tumor. There was no definite grouping of pigmented cells about capillaries, as in Horn's case; hence the occurrence of pigment could not be explained as in his case, by supposing the cells to have derived their pigment from extravasated blood. The cells of the tumor were large; they were round, oval, polyhedral, with large distinct nuclei. The specimens presented were stained with hæmotoxylin and eosin, and with Van Gieson's picro-acid fuchsin. The tumor undoubtedly had its origin in the connective tissue of the papillæ of the mucous membrane and was spreading by continuity of tissue, showing no tendency as yet to involve the muscular wall.

Varieties of the Bacillus Diphtheriæ Fatal to Guinea-Pigs without the Production of the Diphtheria Toxin.—Dr. W. H. Park presented a paper written by Miss Louise Dudley Davis. It was entitled "Preliminary Report on a Bacillus Resembling the Bacillus Diphtheriæ Found in Certain Scarlet-Fever Cases." The writer stated that during the past winter cultures had been taken from many cases of scarlet fever at the Willard Parker Hospital in order to demonstrate the presence or absence of streptococci. In one case of ear abscess, complicating scarlet fever, the examination of the discharge unexpectedly revealed a short bacillus, resembling that of diphtheria. In a second case of ear abscess this bacillus was also found. Agar plates showed spreading colonies with light, uneven edges, and dark centres, but the growth was a little heavier than that ordinarily presented by the diphtheria bacillus. The presence of the bacillus in these two cases resulted in the taking of cultures from other cases of suppurative otitis media—twelve in all. Smears from all these cultures showed short bacilli, staining irregularly. In ten cases the bacillus was isolated from cultures taken from the ear abscess, and in all but three of those taken from the throat also. Unfortunately in these three the cultures were taken some days later than were those from the ear. All of the cases presented clinically typical appearances of scarlet fever, but the unusual proportion of suppurative otitis media was worthy of note, and might have some connection with the presence of this bacillus. One case developed a membranous exudation in the throat, which gave a culture closely resembling that of diphtheria; but no other cases of diphtheria were in the wards, and the patient recovered quickly. A pig, inoculated subcutaneously with two cubic centimetres of the culture from Case II., died twenty-four hours afterward, and the autopsy showed a general serous peritonitis and marked congestion of the kidneys, liver, and spleen. Plates and cultures from the heart's blood, organs, and tissue at the point of inoculation, showed pure and abundant cultures of this bacillus. The absence of the usual lesion of diphtheria and the presence of signs of septicæmia made the experiment one of great interest. The original culture soon lost in virulence, so that eleven cubic centimetres was necessary to cause death. The bacillus was non-motile, produced acid in glucose bouillon, and did not form gas in fermentation tubes. It produced a general septicæmia, and did not form diphtheria toxin, as shown by the fact that diphtheria antitoxin seemed to hasten rather than retard the death of the pigs. It had not yet been determined whether it produced a toxin of its own, but it seemed probable that it did not do so to any marked degree. The questions which very naturally arose, and which had not yet been answered, were: Was this bacillus an attenuated diphtheria bacillus? Was it a variety of that group? Was it an entirely distinct organism?

Dr. Park also read a communication for Dr. Anna Williams regarding a bacillus possessing characteristics similar to those of the bacillus studied by Miss Davis. This bacillus was obtained from the throat of an individual about six weeks after recovery from diphtheria. The organism was morphologically and culturally similar to a typical diphtheria bacillus. In small doses it proved non-virulent for medium-sized guinea-pigs, but by very large doses (ten cubic centimetres of a forty-eight-hour broth culture in which were mixed the twenty-four-hour cultures from three serum and three agar tubes) death was produced. On autopsy the bacillus was found in all the organs. The inoculation of a quantity of antitoxin sufficient to protect against two hundred thousand times the fatal dose of diphtheria toxin, did not protect the animals against one fatal dose of this bacillus.

Diphtheria Bacillus No. 8.—Dr. Park said that on August 28, 1895, a bacillus had been isolated from a case in which the clinical diagnosis was "tonsillitis." This had proved to be the most virulent bacillus they had ever found, and was possibly the most virulent that had been met with anywhere. It had been sent to numerous laboratories in different parts of the world. This bacillus would kill a medium-sized guinea-pig in a dose of one-two-hundredth cubic centimetre. By keeping it at a temperature of 36° C. and transplanting in bouillon every four days, it had been possible to maintain the same virulence now for nearly three years. The cultures used for toxin production had never been passed through animals.

Dr. Prudden said that this communication emphasized the difficulties felt by all bacteriologists regarding what should be termed "species" in bacteria. Two of the speakers had taken refuge, as most did, behind the term "groups," and perhaps this was as secure a position as it was possible to maintain at the present time. The report, just published, of the committee of the American Public Health Association probably gave the fullest and most carefully considered data for the observation of species. Another point of interest in connection with the paper was the extreme delicacy of the physiological test. Even bacteriologists did not always realize what an extremely minute chemical difference in the biological qualities of the bacteria determined whether or not the product should be poisonous. In some respects this physiological test was the most delicate one in our possession.

Dr. Power said that he had four clinical cases during the past winter in the same family, which were of interest in this connection. The first patient, while away from home in Newark, received antitoxin, though the culture from the throat was reported to be negative. This person recovered and returned home to Montclair. The second patient promptly became sick and came under the speaker's care in the Mountainside Hospital. The patient was very ill, although antitoxin was given, and became severely paralyzed. Two other members of the same family were admitted at the same time with a large amount of membrane in the throat. They were injected with antitoxin earlier than the preceding, and had no paralysis. In none of the four cases were any typical diphtheria bacilli found by the examiners in two health-board laboratories, but streptococci were found in each case.

Focal Necrosis in the Liver, Following Measles in Young Children.—Dr. Rowland G. Freeman presented this paper. He said:

"The action on man and the lower animals of the toxins produced by bacteria without the presence of the bacteria themselves has received much attention recently. Focal necroses have been observed resulting from the toxins of diphtheria, typhoid fever, acute lobar pneumonia, malaria, streptococcus infection, and Asiatic cholera, and the lesions produced have been found to belong to the same general class. Moreover, two toxalbumins of vegetable origin, ricin and abrin, have been found to produce similar lesions. This

subject has been recently carefully studied and investigated by means of animal experiments by Dr. Simon Flexner, of Johns Hopkins' University (Johns Hopkins' Hospital Reports, vol. vi., 1897). The lesions produced by these poisons are widespread, involving the lymphatic system and the different viscera. The gross changes found at autopsy are, however, not usually very characteristic. The lymph nodes are enlarged, particularly near the point of invasion. The liver is often congested and is apt to show fatty change. On the surface as well as on the cut surface there may be seen small white or yellow dots, round or oval in shape, which are not elevated and which vary in size from mere points to areas ten millimetres in diameter. These dots are due to areas of focal necrosis. The small areas of focal necrosis do not produce lesions visible to the naked eye. When distinct, these spots are distinguishable from other similar lesions. In the other organs there are no characteristic gross changes. Congestion may be present. The change which occurs in the lymph nodes or in any of the viscera is that of cell necrosis in the different stages and involving either isolated cells or groups of cells. These changes involve first a swelling of the cell body, the cytoplasm becoming more homogeneous and more refractive, and acquiring an affinity for acid dye (eosin). The cell nuclei first stain more deeply and later lose their staining properties. Fragmentation of the nucleus is frequently seen. In some areas of focal necrosis many of these changes may be studied, the periphery of the area furnishing the earlier lesion while the central part furnishes later stages. This condition, although it has been described as following a number of acute diseases, as just enumerated, has not, so far as I know, been described as following measles. It has therefore been thought that examples of it following this disease may be of interest.

"An epidemic of measles occurred at the New York Foundling Hospital the early part of last winter, the characteristics of which have been described by Dr. W. P. Northrup (*Medical News*, 1898, vol. lxxi., No. 26). It was on the whole more mild than previous epidemics of the same disease in that institution, showing a mortality of only 13.9 per cent. It was not, however, free from cases showing very severe complication, such as gangrene about the mouth, ear, vulva, and anus. In all, twenty-five cases came to autopsy. In the first eleven of these cases no evidences of toxalbumin intoxication were noted, nor were they particularly looked for. The twelfth case, however (the liver of which I pass around), gave such evidence of some unusual lesion that the diagnosis was readily made and all subsequent material was carefully looked over and preserved for microscopic examination. Of the fourteen cases which then came to autopsy, including the first case which was recognized as focal necrosis, in twelve specimens were preserved, cut, and examined, and it is these twelve cases which I report. Of these cases four gave distinct focal areas of necrosis of the liver. In three of these the areas were frequent and quite typical. In the fourth case, although ten separate pieces of liver were cut, only one area of focal necrosis was found. In one of them similar areas were present in the Malpighian bodies of the spleen. In these four cases the patients varied in age from eight months to three years. They died at periods ranging from eleven days to thirty-three days after the onset of the measles. One of the patients was not very severely sick and at the end of two weeks seemed to be convalescing, and remained fairly well for two weeks more when the temperature rose to 104° F.; râles appeared in the chest, and death followed three days later. Of the other three cases all had broncho-pneumonia; one had an ulceration near the anus, and another gangrene of the vulva."

Dr. Prudden said that when such lesions of the nervous system as disseminated sclerosis occurred in later life, and an attempt was made to trace them back, measles was apt to be overlooked. This disease, as well as other more immediately serious infectious diseases, might prove a possible origin of some of these obscure lesions of later life.

Dr. J. H. Larkin said he had been struck by the fact that in the focal necrosis found in measles, as just described, there were very few areas as compared with the number observed in other diseases, *e.g.*, typhoid fever. Nor did he see in the specimen presented that peculiar form of focal necrosis found not infrequently in typhoid fever, in which there was a large area around the hepatic vein, and the liver cells were dead and the nuclei had disappeared. This form could be produced experimentally, which was not the case with the form described in Dr. Freeman's paper. If the focal necrosis in these cases of measles was produced by the toxins, the latter must be much milder than those producing focal necrosis in diphtheria and typhoid fever.

The society then went into executive session.

Clinical Department.

FUNCTIONAL ACTIVITY OF THE MAMMARY GLANDS IN AN INFANT.

By J. B. GROVER, M.D.,
PECKVILLE, PA.

The following case is so unusual that I think it will be of interest to place on record. It is that of a female child, born January 28, 1898, having two unusually developed mammary glands (the nipples especially so), which secrete milk so abundantly that the mother is obliged to pump the milk out of both glands at least once daily. The child is fretful until this is accomplished. This secretion of milk began when the child was one week old. The mother pumped the milk out in my presence one morning, and the amount obtained was about two fluid drachms. Macroscopically it had the identical appearance of mother's milk; I did not examine it microscopically. The child is robust, and has the general appearance that healthy babies have at her age.

A CASE OF TUBAL PREGNANCY.

By E. J. WHITEHEAD, M.D.,
COLUMBIANA, OHIO.

Mrs. W—— is a healthy woman, twenty-seven years old. She has been married three years, but has never been pregnant. Menstruation, although somewhat painful at times, had always been regular, until last September. After a delay of eight days it appeared in normal amount, but continued for nearly a month, gradually decreasing, but never stopping entirely. At that time no vaginal examination was made, but she was given a mixture of ergot and hydrastis. This was continued for two or three weeks, with no benefit except a slight diminution in amount of the flow.

Examination then showed the uterus in normal position, but the cavity measured three and one-half inches. At the left side of the uterus, and so close as to seem part of it, a round, hard tumor about as large as a walnut could be felt. This had grown so rapidly in the next two weeks that a diagnosis of extra-uterine pregnancy seemed justified, although the material removal by the sharp curette did not appear to resemble the decidua sufficiently. The immediate effect of the slight curetting was to stop the hemorrhage for about a week.

There was such a noticeable increase in the size of

the tumor that it seemed unwise to delay operation any longer. An incision four inches long was made in the median line, every possible precaution to insure asepsis being used. There was no great difficulty in removing the tumor, which proved to be a tubal pregnancy. After the removal of at least a handful of small blood clots the pelvic cavity was flushed with hot sterilized decinormal salt solution. The wound was closed with ten silkworm-gut sutures. The divided ends of the tube were tied with catgut sterilized in formalin. The abdominal wound was dressed in the usual manner. No drainage tubes were used.

The next morning the usual nausea from ether, instead of ceasing, had become much more severe. There was vomiting of bile-stained mucus. Pulse, 150; temperature, 100° F.; with severe pain throughout the abdomen. At 9:30 A.M. the patient began taking calomel ($\frac{1}{10}$ gr.) every half-hour; this was continued until 6 P.M., when she took a large dose of a saturated solution of magnesium sulphate. At 8 P.M. the pulse rate was 160; temperature, 102.4° F. During the night two enemata of magnesium sulphate were administered, owing to the fact that it was impossible to give any remedies by the mouth. About once in four hours she had a hypodermic injection of strychnine, gr. $\frac{1}{30}$.

During the second night she obtained no sleep. In the morning the temperature was 100.4° F.; pulse, 150; respirations, 26. As the vomiting had ceased, she was given beef juice in small amount at frequent intervals.

In the afternoon the bowels moved. The temperature then began gradually to decline, and within twenty-four hours was less than 100° F. Thereafter convalescence was rapid and uninterrupted. The dressings were removed on the ninth day. The wound was found entirely healed, except where two of the sutures had become partly untied, possibly because of the severe strain during vomiting the day after the operation. She was out of bed two weeks after the operation.

OBSTRUCTION OF THE ŒSOPHAGUS.

By J. D. LOUIS, M.D.,
ST ANTHONY, IDAHO.

On Tuesday, August 3, 1897, I was called to see Mrs. W——, aged thirty-six, by her husband, who stated that she had been suffering since the Sunday night previous with an obstruction of the œsophagus. He gave me the following history: Mrs. W——, when a little girl, had swallowed some concentrated lye, and very narrowly escaped with her life. Since that time she had been very careful about her eating, and did not partake of the more solid foods, but limited her diet to liquids and spoon victuals. She had suffered from an obstruction on one occasion before I saw her, which had been removed with difficulty.

On arriving at the bedside, I found the patient suffering with nausea, which had been present almost continuously since the Sunday night previous to my visit. She was eight months pregnant, and greatly worried for fear she would have a miscarriage. She stated that she had been unable to get water to pass the obstruction, which she said consisted of boiled potato.

After making a thorough examination and failing to pass an instrument, I decided to try hydrogen dioxide, believing that, in connection with the saliva which was incorporated with the bolus, an effervescence would be produced, thereby dislocating the obstruction. After she had taken one teaspoonful she was able to pass water into the stomach, and after using an ounce of the hydrogen dioxide the obstruction was entirely removed. She has since had no recurrence of the trouble.

EXCISION OF THE RIGHT SHOULDER-JOINT FOR SUBCORACOID DISLOCATION OF THE RIGHT HUMERUS, COMPLICATED BY AN I-FRACTURE OF THE SURGICAL HEAD.

By CHARLES VOORHEES BUTTLER, M.D.,
VISITING SURGEON TO THE WILLIAM W. BACKUS HOSPITAL, NORWICH, CONN.

On May 28, 1897, Mrs. C——, forty-two years old, of this city, came to the outdoor department of the hospital for treatment on account of an injury to her right shoulder. About five weeks previously she had fallen from a doorstep, with her arm behind her back, striking on her right shoulder. Considering it only a bruise, the arm having been greatly discolored, she did not consult a physician, but was obliged to do so at last on account of the disability, she not being able to raise her arm farther than to an angle of 45°. She was greatly crippled in her work, being a hard-working laundress. Dr. Higgins, the house surgeon, examined her and found a subcoracoid dislocation of the right humerus. The next afternoon I made an attempt to reduce the dislocation, and, the patient being etherized, I carefully rotated the arm so as to break up any adhesions that might have formed. After rotation for a short time, crepitus was felt over the head of the bone, which was distinctly communicated to the elbow-joint. All manipulations were immediately stopped and the diagnosis was then made: Subcoracoid dislocation, complicated by a fracture of the anatomical neck. The neck of the bone had evidently been fractured at the time of the dislocation, for all manipulations were done so carefully that we could not have fractured the neck of the bone, but probably by rotation had caused the breaking up of whatever callus had formed. A consultation of the visiting-staff was called, and it was decided that an operation would be necessary to give the patient a better arm than she then had. Even if the fracture united with the head of the bone dislocated, the chances were not favorable that she would have much use of her arm. Three attempts were made by Dr. W. T. Browne, of this city, to take an *x*-ray photograph of the shoulder, but on account of the breaking of the only Crookes tubes that were in this city, we were unable to obtain the skiagraph.

On Saturday, June 5th, I operated in the presence of the staff, with the idea of replacing the head of the bone in the glenoid cavity and then attempting to get union of the fracture, wiring if necessary; if this was impossible, to exsect the head of the bone. A longitudinal incision was made, five inches in length, commencing about one-half inch external to the coracoid process of the scapula. After separating the fibres of the deltoid muscle, I found the head of the bone under the coracoid process; the capsule was intact, but so bound to the adjacent structures that it was necessary to supplement the original incision by a horizontal one, two inches in length, parallel to the clavicle. On opening the capsule, which was greatly thickened, I found the articular surface turned at nearly a right angle from its proper relation to the shaft. The fracture was I-shaped—the upper bar at the rim of the articular surface; the lower, at the junction of the tuberosities and the shaft; the upright, joining the two, between the tuberosities. The fragments were separated to the extent of admitting the tip of the index finger, and the long tendon of the biceps muscle was caught in the longitudinal fracture, and was with great difficulty separated without further injury. A moderate amount of callus was present, showing that an attempt at union had been made. The fragments were softened, showing that they were evidently undergoing necrosis. On account of the condition of the head and anatomical neck of the bone, it was decided to remove the fragments and to replace the humerus

as near to its proper position as possible. The fragments were removed, as much of the capsule and periosteum being saved as possible. The wound was cleansed, stitched up, drained through incision, and the arm bandaged against the side of the chest with an axillary pad, the forearm being flexed to a right angle.

On the third day, as the wound was not draining properly and as the patient's temperature was rising, it was evident that freer drainage should be had. The patient being etherized, a small incision was made posteriorly and a tube was passed through the joint.

Mrs. C——'s recovery was retarded by repeated attacks of rheumatism, notwithstanding which the wound healed nicely and she was discharged from the hospital on July 28th. She was readmitted to the hospital for another attack of rheumatism on September 13th, and discharged well on November 17th. On March 12, 1898, I examined her, and she is now able to use her arm to wash and iron, needing a little assistance to raise heavy articles. The arm can be passively abducted to more than a right angle, and she is entirely free from pain when the arm is moved actively or passively.

A CASE OF DELAYED CHANGE OF VOICE, DUE TO UNRECOGNIZED POWER TO USE THE ADULT VOICE.

By H. SCHOONMAKER, M.D.,
ROCHESTER, N. Y.

The history of this case is that from about two years of age the boy had an unusually high-pitched voice and was subject to hoarseness and huskiness. During childhood he had many attacks of acute and subacute coryza, with a resulting nasal obstruction sufficient to cause mouth breathing. At twelve years of age—about two years ago—signs of change of voice were noticed along with the other changes of approaching puberty. At this time he occasionally used the deep tone, but soon abandoned it altogether, developing instead a squeaky, rasping, high-pitched voice, it being at times but a hoarse whisper. The boy being naturally diffident, this condition led him to speak only when necessary. He was placed under the care of a specialist, who relieved the nasal obstruction and consequently the mouth breathing. He did not, however, benefit the voice condition.

In addition to the special treatment he had been under the observation of the family physician for a long time. Both physicians are men of undoubted ability.

He came to me about four weeks ago. The vocal cords were somewhat roughened and thickened, but, in view of the fact that the other changes of puberty had occurred, it seemed impossible to understand why he should not use the adult voice.

My plan of treatment was to spend an hour more or less with him every day in trying to teach him control over his vocal apparatus, by much the same methods that a music teacher uses in voice culture; also to use medicated vapors, respiratory gymnastics, and any other means whereby the vocal apparatus might be strengthened. I confess I had not much faith in the effort. After four days (and this is the interesting part of the case), by gaining the lad's confidence and dispelling as well as I could his diffidence, and by questioning him carefully concerning the period when his voice should have changed, I discovered that his voice had already fully changed, but that he did not know it. This discovery simplified matters decidedly. I now showed him that if he would will to use the deep voice, he could do so. This he has done, until now the act of the will has become automatic. For a few days after recognizing his power to use the "deep manly voice," if he spoke without conscious effort, he would use the old voice.

We occasionally meet a man whose voice has the same pitch as before puberty; and my experience in this case leads me to ask the question: May not this condition be due to an unrecognized and neglected power at puberty?

235 Lake Avenue.

HÆMATEMESIS AS A SEQUENCE OF CHRONIC ULCER.

By GEORGE FLANAGAN SHAW, C.M., M.D.,
ST. ANDREWS, P. Q., CANADA.

Four and one-half years ago I had under my care a girl, aged seventeen years, who suffered from an extreme degree of chlorosis, including a well-marked hæmic murmur, heard most distinctly in the left second intercostal space. She was put under careful treatment, and soon the dyspnœa, pallor, palpitation, and murmur disappeared; the menses resumed regularity and quantity, the appetite became good, and the system generally regained its normal vigor. It was then hoped (and with good reason) that a permanent change had been brought about, and that every danger had been passed. For two years, indeed, our expectations were confirmed, and no complaints were heard. During the six months following the two years referred to, I was again consulted by her for shortness of breath and loss of appetite. I again resumed treatment and in addition advised a change of scene, which latter suggestion she acted upon. Her recovery now was rather more tedious than before, yet in a reasonable time every untoward symptom passed away, and she again had nothing to complain of until her present illness, which brings forth this report. About ten days ago I was hastily summoned to her bedside, and upon arriving I was informed by the mother that my patient had just had "a great bleeding from the lungs," and that "the worst fears were now confirmed; the dreaded consumption had marked her daughter for its victim." I was then shown two large wash basins, one of which was found to contain a pint and one-half of dark, grumous, fluid blood, with scarcely any food débris; and the other three-quarters of a pint of the same discharge. The patient was very much blanched and very weak, though not suffering from any nervous shock. The pulse was soft, easily compressible, and much wanting in volume, and the breathing somewhat hurried and shallow. Later on in the day when any immediate danger seemed past, the patient informed me that she had been very well previously, taking part in various social functions, and was in the act of preparing for such an event (which involved a drive of a few miles) when an agonizing pain set in in her stomach and radiated to the lower abdominal zone. She then became dizzy, and with a feeling of faintness staggered toward her bed, at the same time calling to her mother and motioning for a basin. What followed the mother has told. "A very cataract of blood" came tumbling from her daughter's mouth, without any seeming effort, necessitating the use of two basins. Simultaneously with this, a small quantity of blood passed per anum. The following day the patient was found to be quite comfortable and cheerful, and she craved food. She informed me that her menses, which were due, had come on during the night. She also mentioned that she had eaten heartily the day before her illness, and that for a few days previously she had noticed a darkening of the stools. Upon examination, the contents of the basins were found to be bloody, and from the stomach, acid in reaction, with corpuscles much disintegrated. The urine was devoid

of any abnormality. The patient is now doing well. This, then, is a typical case of latent chronic ulcer of the stomach, with an example of one of its most dangerous sequences, and in which previous symptoms were entirely disguised during the whole course. Repeated questioning and careful examinations had been carried on from time to time, during a period of four years or more, and nothing was elicited to base a diagnosis of ulcer upon. The pathology of such cases in chlorotic girls seems to be wrapped in obscurity, and much has yet to be learned concerning the exact causes and process of initiation. The enormous quantity of blood lost to the circulation in a short time is not too often associated with recovery, especially when from a young girl under one hundred and ten pounds body weight.

Therapeutic Hints.

Bronchorrhœa.—

℞ Benzoic acid..... 0.13
Tannin..... 0.15
For one powder. Make twenty. Take four daily.

—Maragliano.

For the Shaking of Paralysis Agitans.—

℞ Strych. sulphat.,
Ac. arsenios..... āā 0.06
Ext. bellad..... 0.3
Quininæ sulph.,
Mas. pil. Blaudii..... āā 2.4
Ext. taraxaci..... q.s.
M. ft. pil. No. xc. S. Three pills daily.

—S. W. Gross.

Rheumatism.—For local application:

℞ Ac. salic. subtil. pulv..... 10
Ol. terebinth..... 10
Lanolin..... 50
M. S. Apply.

—Husson.

In Nerve Weakness and Anæmia.—As a substitute for Brown-Séquard's organic preparations:

℞ Calcii glycerophosphat..... 1
Ac. nitric..... 0.1
Sacch..... 6
Aq..... 34
Shake and boil. S. Three times a day a dessertspoonful.

Or:

℞ Calcii glycerophosphat..... 0.15–0.3
Ol. theobrom..... 0.1
For one pastille. Take four such daily.

Or:

℞ Ferri glycerophosphat..... 2
Aq. cinnamomi..... 40
Syr. aurantii..... 100
M. S. Dessertspoonful at dose.

Or:

℞ Ferri glycerophosphat..... 10
Vini Madeiræ..... 1 litre.
Macera per horas xxiv. et filtra. S. Before each meal a wineglassful.

—*Allgemeine medicinische Central-Zeitung*, No. 81, 1897.

Yellow Fever.—

℞ Sodii bicarb..... gr. cl.
Hydrarg. chlor. cor..... gr. ½
Aquæ..... ℥ xl.
M. S. Three tablespoonfuls every hour.

—Sternberg.

Blepharitis.—

℞ Hydrarg. oxid. flavi..... gr. x.
Vaselini albi..... ʒ ss.
Smear along the lid margin morning and night.

In hyperæmia of the lid border with crusting the crusts may first be rubbed off with cotton wool soaked in a little spirits and water (about one part of whiskey to three of water), and then the following ointment rubbed in:

℞ Ichthyoli..... ♏ ij.
Aquæ destillatæ..... ʒ ss.
Lanolini..... ʒ ss.

Essential Neurasthenia.—1. Douche in broken jet over the trunk, in full jet over the limbs. Ten seconds' duration. Avoid douching the head. 2. Before each meal quassia macerated in red wine. 3. Iron preparations. 4. On retiring:

℞ Potass. brom..... 50 gm.
Sodii brom.,
Ammon. brom..... āā 20 "
Aq..... 1,000 "
M. S. Two soupspoonfuls.

Or:

℞ Sulphonal..... 0.50 cgm.
In two doses with an hour's interval.

Before each meal three of the following pills may be taken:

℞ Quininæ hydrobromat..... 0.05
Ext. valerian..... q.s.
For one pill.

—Charcot.

Pneumonia.—

℞ Ammonium chloride..... gr. x.
Ammonium carbonate..... gr. v.
Ammonium salicylate..... gr. v.
Fluid extract of coca..... ʒ i.
Essence of pepsin..... ʒ i.
Syrup of tolu..... ʒ i.
Water..... ʒ i.
M. To make a tablespoonful, which is to be given with or without water every second or fourth hour.

—S. Solis Cohen, *Philadelphia Polyclinic*, January, 1898.

Acute Gingivitis.—

℞ Tinct. myrrh..... 10
Eucalyptol,
Menthol..... āā 0.25
Sodii biboratis..... 10
Aquæ destillatæ..... 200

—*Allgemeine medicinische Central-Zeitung*, March, 1898.

Pertussis.—

℞ Tinct. belladonnæ,
Tinct. aconiti..... āā 5–10 gtt.
Aquæ chloroformi saturat.,
Syrupi althææ..... āā 30
Aquæ destillatæ..... 90
S. Teaspoonful every two hours.

—Perier.

Benzoate of Sodium in the Treatment of Grippe.—It may be given in capsule or powder form, the usual dose being ten grains, three or four times a day. When muscular symptoms are pronounced, the following combination acts admirably:

℞ Sodii benzoatis..... ʒ ij.
Salol..... ʒ i.
Phenacetin..... gr. xxxvi.
M. et ft. chart. No. xii. S. One powder every four hours.

—*Gaillard's Medical Journal.*

Gonorrhœa.—When early, simple, and uncomplicated use for injection:

℞ Zinci iodidi..... gr. x.
Zinci chloridi..... gr. ij.
Aquæ..... ʒ vi.

Use a hard-rubber syringe holding at least three drachms, and having a nozzle at least one-half inch in length. Let the injected fluid go as far as it will.
—Frank Glenn, *Indiana Medical Journal*, January.

Warburg's Tincture.—We have received a request to give the formula for this remedy. Many simpler ones are in use, but the formula as originally given by Dr. Warburg himself is as follows:

℞ Socotrine aloes ..... ℥ xij.
Rhubarb,
Angelica seeds,
Confect. Damocratis ....āā ℥ i.
Elecampane,
Saffron,
Fennel,
Prepared chalk .....āā ℥ ij.
Gentian root,
Zedoary root,
Cubebs,
Myrrh,
Camphor,
Larch boletus .. ..āā ℥ i.

Digest in five hundred fluid ounces of proof spirits in a water bath for twelve hours; express, and add quinine sulphate, ℥ x.; place in a water bath until the quinine is dissolved; cool and filter.

Diabetes.—Uranii nitratis, gr. i.–ii. Give three times a day in plenty of water, and increase gradually to a maximum daily dose of from ten to twenty grains.

Coryza.—

℞ Uranii acetatis ..... 1–2 parts.
Aquæ destillatæ..... ... . 20 "
M. S. Snuff up two or three drops daily.

—*Revue Médicale*, January 21st.

Enteroclysis in the newborn, when stools are very fetid:

℞ Naphthol..... 1
Borax..... 10
Water..... 1,000

—Bonnaire, *Gazette Médicale de Liége*, October, 1897.

Modified Milk—A home modification of simple form is the following:

℞ Cream (12 per cent.)..... ..... 7¼ oz.
Whole milk ..... 5⅛ "
Lime water .... 2 "
Sugar of milk (dry) .... 1¼ "
Water ..... 22⅜ "

—Westcott, *Archives of Pediatrics*, January.

Tuberculosis.—Ichthyol acts more energetically than creosote. Begin with two grams daily and increase to four at the end of a week.—Fraenkel, *Therapeutische Wochenschrift.*

Within two years thirty absolute and unequivocal recoveries have been recorded under the use of antiphthisin (Klebs).—J. H. Williams.

Chronic Rheumatism.—

℞ Acidi salicylici..... gr. v.
Cimicifugæ ..... gr. ij.
Potassii iodidi..... ..... gr. iss.
Tinct. gelsemii..... gtt. i.
Elix. simplicis..... ℥ i.
M. S. One dose.

Coryza.—

℞ Cocainæ hydrochloratis..... gr. iiss.
Mentholis ..... gr. iv.
Acidi borici..... ℥ ss.
Pulv. caffeæ ..... gr. viij.
M. S. Snuff up a pinch three or four times a day.

—H. B. Whitney.

Or, to prevent and ward off tracheitis, use hot boric-acid solution by means of a nasal douche at the onset of symptoms.—Courtade.

Uræmic Dyspnœa.—When severe, inject every hour, day and night, two cubic centimetres of ether. Or give by the mouth in sweetened water.—Lemoine, *La Presse Médicale*, No. 84, 1897.

Angina Pectoris.—The iodides check and modify the progress of arterio-sclerosis and lower blood pressure.

℞ Potassii seu sodii iodidi..... gr. x.–xv.
T.i.d. for a long time.

—Osler.

Formula for Pastilles.—Dr. A. F. R. Nalk (*Ugeskrift for Läger*, No. 28, 1897) gives the following formula for a chewing-pastille, to be used in pyrosis, heartburn, or for other purposes by modifying the ingredients:

℞ Massæ gummi ad manductionem..... 100
Oxidi magnesii lev.,
Phosphat. magnes. ammon..... .āā 1
Rhiz. zingiberis pulv 0.15
Cort. cinnamomæ pulv..... 0.3
Sacch. alb. 0.07
Ft. pastillas No. 200.

For those who have bad teeth or cannot chew, he uses "trochisci alcalici," made as follows:

℞ Phosphat. magnes. ammon..... 7
Magnesii oxidi,
Sodii bicarb.....āā 4
Sacch. lactis..... 30
Sacch. albi 140
Tragacanth 1
Æther..... gtt. ij.
Tinct. zingiberis..... gtt. xij.
Mucil. gummi arab.,
Aquæ destil ....āā p.æ.
M. ft. s. art. trochisci No. 100.

Perniones.—

℞ Ichthyol..... 1–5
Resorcin..... 1–3
Adipis lanæ..... 25
Ol. olivæ..... 10
Aquæ destill.....ad 50
S. Apply at night.

—Jadassohn, *Allgemeine medizinische Zeitung.*

Acute Gastro-Enteritis of Children.—

℞ Rad. calumbæ..... 1
Aquæ..... 75
Ft. infus.; adde:
Bism. subnitr..... 3
Syrup. flor. aurant..... 15
S. Teaspoonful every two hours.

—Trabaudt, *Correspondenzblatt für Schweizer Aerzte.*

Medicines which are Forbidden during the Period of Lactation.—Dr. Boissard (*Journal de Médecine de Paris*, ix., April 6, 1897) sums up the above subject as follows: "The medicines which are not to be given internally include those which influence unfavorably the quantity and quality of the milk, and further those which permit the return of the menses. For that reason all drastics which give rise to a congestion of the genital apparatus are to be forbidden. In persons who have their courses again and who suffer from profuse bleeding, rest in bed and hydrastis are to be used, and not ergotin, ergot, or digitalis. Avoid diuretics and diaphoretics; thus forbid digitalis, pilocarpine, and asparagus. In cases of constipation use regulated diet, castor oil, or cascara; exclude salines, podophyllin, rhubarb. The use of alcoholic drinks is absolutely to be forbidden. Sulphate of quinine enters the milk in such a small amount that it may be ordered if necessary. Preparations of opium and arsenic are to be avoided, however; camphor and antipyrin appear to influence the secretion of milk unfavorably, and therefore are not to be used."

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GREAT BAZAAR FOR THE LONDON HOSPITAL—THE PRESS AND ITS LITTLE PAPER—THE MEDICAL COUNCIL'S PROSECUTIONS—DOCKRELL VS. DOUGALL—A SOCIETY TO PROMOTE THE KNOWLEDGE OF TUBERCULOSIS.

LONDON, July 1, 1898.

THE one absorbing topic of the week in professional circles, as well as in the most aristocratic society, has been the great press bazaar held in the Hotel Cecil on behalf of the London Hospital. This is, as you probably know, our largest hospital, and contains about eight hundred beds. It is located at the East End, amid a poor and crowded population and near the docks. There is always a great demand on its accommodation, and as it is not endowed there is a chronic difficulty in its financial resources. This year it was proposed to organize a great bazaar on the part of the press in support of the funds, and a wonderful success it has been. All the leading papers have taken part in the work. High Tory, moderate Conservative, Unionist, Liberal, Radical—all shades of political opinion have united for once to boom the East End charity, and the representative organs of these opposing views have urged its claims on their readers. The preparations have been going on for many weeks, and at last the idea has been realized.

The bazaar was opened on Tuesday afternoon by the Princess of Wales, accompanied by the Duchess of York, and continued on Wednesday. There was a very fine programme of dramatic and musical performances, commencing with recitations by Sir Henry Irving and Miss Ellen Terry. At each stall duchesses and other ladies were disposing of the articles they had accumulated in the usual manner of bazaars, at prices in excess of those anticipated at such assemblies. At one stall you could buy tea cloths, each bearing the signature of some royal or distinguished personage. One was signed by the Princess of Wales, another by Mrs. Gladstone. Books were on sale at another stall, many beautifully bound, each copy being signed by the author. Signatures were, in fact, at a great premium, and it was reported that an ordinary luggage label signed by a popular actor was sold for half a guinea! The new craze for old dramatic posters was also in evidence. A first edition of "Paradise Lost" was an attraction at one stall.

The bazaar was in communication with all the theatres and music halls by the electrophone, and the throngs of visitors were able to listen to the voices of Mr. Gladstone and other celebrities through the phonograph.

A striking feature was the palmarium, where visitors could take ices, strawberries and cream, and so on, beneath gigantic palms interspersed with electric lights, while they listened to a stringed band and the plash of water in the fountain or gazed curiously on the throng of celebrities.

That curious survival of superstitious absurdity, called "palmistry," was in full force, and credulous ladies were able to show their delicate hands and hear the "palmist" tell their fortunes on terms which would make the poor gypsy's mouth water. But we fine the gypsy who persuades an ignorant girl to cross her hand with silver, while her richer sisters can carry on their deceit under the ægis of the press. "All for the charity, and of course it is only nonsense," said one; but I know educated ladies who are influenced by this folly. The gambling spirit of the age found vent in the usual devices employed on these occasions, and visitors enjoyed the mild stimulus of losing their money for the benefit of the sick poor.

The success of the bazaar has equalled the expectations of its promoters, and will give about £10,000 to the London Hospital.

A unique feature of this remarkable entertainment, and one which will interest you as an editor, was the establishment of a daily newspaper on a scale never before, I believe, attempted, and to last only for two days. This was called the *Press Bazaar News*, and the two copies lie before me. It was produced in a room which would not accommodate a third of its staff; for although one compositor sufficed to set up the little four-page sheet, it boasted of engaging the thoughts and care of nearly two hundred editors and contributors! A linotype machine was set up for the work, and here a curious difficulty arose. The furnace to melt the metal for this might be a source of danger, and the catastrophe of the Paris Charity Bazaar be repeated. Accordingly electricians were appealed to, and contrived a furnace for the occasion which completely solved the problem of melting the metal without an open fire. With the enterprise thus displayed, you may imagine that other mechanical difficulties were fully met.

Among the editorial arrangements, science was committed to the care of Dr. Hopkinson and Mr. T. A. Edison, while Mr. Herman E. Dick undertook to advise them of the developments that occurred on your side of the water. Col. John Hay, the United States ambassador on this side, accepted the post of American correspondent, and his daughter contributed a poem to the paper. Art criticism was intrusted to Lord Ronald Sutherland Gower, the sculptor of the Shakespeare memorial at Stratford-on-Avon; music to Sir A. Sullivan, and the Wagnerian department to Lady Charles Beresford; the drama to Sir H. Irving (who contributed a criticism on one of his own performances) and Miss Ellen Terry. These are samples of the literary staff. In politics Lord Dufferin was foreign editor, and Lord Charles Beresford undertook naval affairs.

The price of the *News* was one shilling each copy—and it boasts of being the dearest and tiniest paper ever produced.

The Medical Council has been defeated in another prosecution. "John Hamilton, M.D., New York," was charged with falsely pretending to and using the title of doctor of medicine, he being unregistered under the medical acts. Mr. Muir Mackenzie prosecuted. The defence was that defendant had never described himself as other than he was, and two previous prosecutions against him had failed. The magistrate said there was no evidence that he had used the title with intent to deceive, and dismissed the summons. The law advisers of the council have not much to boast of, though no doubt they do their best. Still their best does not seem so successful as the methods of the Defence Union. What seems to be wanted is some further legislation to make it clear that an unregistered person is liable to the penalties for engaging in practice. A foreign gentleman with a genuine Vienna degree was lately convicted, and this man escapes. The "glorious uncertainty of the law" may well be a proverb.

Another legal case is of interest to the profession. Dr. M. Dockrell sued one Dougall for libel, in that the latter had circulated statements to the effect that the doctor prescribed "Salyco water" for habitual use, and had said, "Nothing has done my gout so much good." This last assertion seems to have been made in conversation with Dougall, the proprietor of the water—and shows how dangerous it is to hold any communication with the venders of any nostrum. Promises to withdraw the circulars were made, but not

carried out, and Dr. Dockrell was obliged to appeal to the law. The water contains colchicine, and the danger of recommending it for habitual use was urged, as well as the injury to any doctor of using his name without authority. The judge said that to order it twice daily for a fortnight, as had been admitted, was equivalent to habitual use! The jury found on this that there was no libel. An injunction to restrain Dougall from using the doctor's name was refused, but there will probably be an appeal, when it is to be hoped that the army of quack-medicine venders will not be authorized to advertise the names of regular practitioners against their consent.

A sort of drawing-room meeting was held last week at the house of Sir W. Broadbent, with a view of eliciting opinions as to whether the time had come for forming a society to disseminate knowledge as to the propagation of tuberculosis. The promotion of sanatoria was also suggested as a possible outcome. The question whether the society in contemplation should be a purely medical one or whether it should embrace others who were interested in the subject was also put before the meeting. As to this, it was urged that the society would strengthen the hands of medical officers of health and that it might be well to enlist the sympathy and co-operation of the chairmen of boards of guardians. It was resolved to form the society, and a provisional committee was appointed to arrange for holding a public meeting.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE NEW INSTITUT PASTEUR — DISPOSAL OF THE BARONESS HIRSCH'S GIFT—BUILDING BEGINS—PROFESSIONAL PARIS BEGINS TO SHOW SIGNS OF THE APPROACHING SUMMER VACATION—AN ADDITIONAL EXAMINATION IN OBSTETRICS REQUIRED TO OBTAIN THE FRENCH M.D. DEGREE—INTERESTING MEETING OF THE MEDICAL SOCIETY OF THE HOSPITALS—MIXTURE FOR GASTRO-ENTERITIS IN CHILDREN.

PARIS, July 2, 1898.

THE lengthy discussion with reference to the disposal of the gift of the Baroness Hirsch has been closed by a decision of the council of administration of the Institut Pasteur. The amount of the gift was two millions, full liberty being left the administration to employ it as they should judge best. Construction of a new biological institute has been after mature deliberation agreed upon as the most wise and useful means of employing the money, and a visit to the institute grounds will now discover the building actually going on in the Rue Dutot. The foundations are laid and the work in general is being actively pushed forward. It will take, nevertheless, two years to finish the new institute; that is, to have it ready for occupancy: and it is hoped to time the inauguration with that of the universal exposition of 1900. The new institute will comprise lecture rooms, amphitheatres, and a hospital, in which cases will be cared for, observed, and studied that it is not desirable to keep in the Institut Pasteur proper.

The new institute will be of immense value to the science and practice of medicine, and will permit us to subtract from psychology and restore to biology the study of certain intellectual and moral functions. These really do not belong to biology directly, but bear the same relation to it that physiological functions do, of which they are the outcome: and the development of this branch of science will have a direct practical application in elucidating the diagnosis and treatment of obscure mental disease. It will be seen that the annex of the Institut Pasteur will be devoted to a higher and greater field of study, embracing more especially the fundamental biological doctrines, with natural philosophy and the real history of the animals as well as man and humanity.

Paris begins to show signs of the approaching end of the academic year, and by the time these lines are read in the MEDICAL RECORD the exodus which is beginning will be in full swing. Professors at the École de Médecine are already admonishing their classes of the close of their courses, and practitioners in the city are informing their patients that the summer vacation is at hand, and that after such or such a day Dr. "So-and-So" will call to see them—when the professor or practitioner will quietly slip off to America or Switzerland to enjoy a well-earned rest from the cares and exigencies of a medical practice.

The new plan of dividing the fifth examination for the doctorate into three parts seems to work very well indeed. It will be remembered that formerly there were only two parts to the fifth, both bedside examinations, followed by questions in another room as regards diagnosis, prognosis, and treatment—the one in medicine, the other in surgery. Now there are three separate examinations, usually a few weeks apart—obstetrical, medical, and surgical—but forming one, the fifth, which is always held at one of the larger hospitals, such as the Hôtel Dieu or the Charité. There was considerable grumbling on the part of candidates when the new law was promulgated, but now it is accepted as a matter of course and cheerfully acquiesced in. It must be admitted that graduates were heretofore sent out without sufficient practical obstetrical examination, the only examination of the kind being the oral one at the third, which was held at the School of Medicine; whereas the obstetrical part of the fifth is held at the bedside, either at the clinique Baudelocque or at the clinique d'accouchements.

The last meeting of the Medical Society of the Hospitals was particularly interesting. Dr. Jacquet presented a syphilitic patient having a gummatous osteitis of the tibia, refractory to very active treatment with mercurial frictions and iodide of potassium, who was cured in several days by an injection of calomel. The nocturnal pains disappeared from the next day, and at the end of eight days the nodosities of the tibia had been resorbed.

In a case of pulmonary gangrene, sufficiently specified by the odor of the breath and by the aspect of the sputa, Dr. Gaillard and Professor Blum performed pneumotomy. The nidus, situated at the right base, was opened by a large incision. It was then established that its volume was that of a fist. The following days the wound suppurated abundantly and its borders reddened. Nine days later the patient died, and at the autopsy they found a pleural suppurative collection, encysted in the anterior portion of the lung, that had escaped operation. Moreover, there was pericarditis. It is lawful to suppose that this patient succumbed to a secondary septicæmia.

Dr. Florand publishes a fresh case of cerebro-spinal meningitis to be added to those that have been previously reported to the Medical Society of the Hospitals by Professor Netter. The latter can affirm in this respect that he to-day possesses thirty-two observations of this kind, collected since his attention was called to the subject.

Dr. Dalché, returning to the communication of Dr. Sevestre at the last meeting, with reference to the cure of meningitis, noted a case observed by himself in an adult, who, during eight days after a pneumonia, had attacks of Jacksonian epilepsy: in this case the hypothesis of a meningeal "plaque" is at least probable. And there is no doubt about the cure, because since that time—and it is now ten years—the subject in question has been entirely free from cerebral accident of any kind.

A good mixture in the acute gastro-enteritis of children is the following, proposed by Dr. Dutt:

℞ Subnitrate of bismuth ..... 2 gm.
Elixir paregoric,
Tincture chamomile.....āā gtt. xl.
Glycerin..... 8 gm.
Distilled cinnamon water..... 50 gm.
M. f. s. a. To be taken by small teaspoonfuls every three hours.

CARBOLIC-ACID INJECTIONS IN CARBUNCLES.

To the Editor of the Medical Record.

Sir: In my late brief contribution to the Medical Record on the above topic, an omission was made which I now hasten to correct. It is this. In my search through the literature on carbuncles, I was unable in any journals, American or foreign, to discover who first employed or recommended the hypodermic injection of pure carbolic acid for this lesion. I am now in receipt of a personal communication from the medical director of the navy, Dr. C. J. Cleborne, United States Naval Hospital, Norfolk, Va., in which he states that he has so employed carbolic acid for more than twenty-five years, and that he was "the first to introduce it to the profession" for treatment of carbuncle.

I notice, however, that he recommends it "in the treatment of buboes, abscesses—in fact, in all collections of pus." My own claim for it was in "carbuncles," in the treatment of which its powers are magical, safe, secure, and permanent in results. The doctor attaches great importance to the necessity of always employing "the pure concentrated carbolic acid," in which I entirely agree, though in my own hands a ninety-five-per-cent. solution has answered equally well. It is scarcely possible that Dr. Cleborne would recommend this potent remedy "in all pus collections." My own impression is that, exclusive of the specific inflammation of anthrax or carbuncle, its employment is of doubtful propriety. For this alone I have ventured hypodermically to employ pure carbolic to the exclusion of all other remedial agents of every description, and hence, until there is proof that there are others in the field who have anticipated on these lines, I must defend my claim of being the first to record the results of carbolic acid in carbuncle.

Thomas H. Manley, M.D.

115 West Forty-Ninth Street, New York.

APOMORPHINE.

To the Editor of the Medical Record.

Sir: Permit me through your columns to indorse the suggestions made by Dr. S. A. Visanska in the Medical Record of July 2d, on the subject of "Apomorphine and its Uses." As regards its use in general practice I have had but little experience, though the physiological action of the drug, as I have often observed it, is undoubtedly such as to warrant its much wider recognition and application by the profession at large. But I wish to emphasize its undoubted value in throat practice. In catarrhal laryngitis, as pointed out by Dr. Visanska, the hydrochlorate of apomorphine is a most valuable preparation. This is especially true in those cases in which the spasmodic attack has been brought on by gastric disturbances.

Another important indication, and one apparently overlooked by the author of the paper, is the presence of a foreign body in the œsophagus. In such a case a hypodermic injection of one-tenth of a grain of the hydrochlorate produces prompt emesis (usually within five minutes). An additional advantage of the emetic is that it does not pass down the œsophagus, sweeping the foreign body farther down, and also that it is non-irritating to the gastric mucous membrane.

I disagree with Dr. Visanska when he says the drug is not well known. Its existence is widely known, and it is treated of in every modern text-book, but for some undiscernible reason its advantages have never been widely recognized; consequently it does not hold the prominent position in practical therapeutics to which its properties clearly entitle it.

J. Wilkinson Jervey, M.D.

Charleston, S. C.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 16, 1898:

	Cases.	Deaths.
Tuberculosis	153	134
Typhoid fever	15	4
Scarlet fever	125	11
Measles	154	10
Diphtheria	172	23
Laryngeal diphtheria (croup)	8	3
Cerebro-spinal meningitis	0	12
Small-pox	1	0
Chicken-pox	4	0

Stuttering.—According to Dr. Gutzmann, whose report has been adopted and published by the German government, involuntary mimicry plays a great part in stuttering. Like yawning it is catching. The quicker a child is and the more imitative, the more apt it is to imbibe any defects of speech on the part of those by whom it is surrounded. Conclusive evidence of the contagious nature of stuttering is to be found in the fact that the number of stutterers in a school increases steadily as the children pass upward from class to class. In the public schools of Berlin, for instance, the number of stutterers among the children in the lower class was 0.52 per cent. of the total force of the class. This proportion rose from year to year, as the children passed upward in the educational scale, until in the highest class the percentage was discovered to be 1.61, or more than three times the number found when the same children were in the lowest class.

New Elements in the Air.—The atmosphere has been made the subject of special study by chemists during recent years. The liquefaction of oxygen, nitrogen, air, and lastly of hydrogen followed closely one upon another, and at the same time made possible the production of an intensity of cold, by means of which many mysteries have been already laid bare and which have also rendered possible the discovery of many other important secrets of immense practical value. Professor Ramsay has now discovered that the atmosphere contains at least two more elements than had been known or suspected. Until quite recent years science stated that air was a mixture of oxygen and nitrogen, together with a small quantity of carbonic-acid gas. To these Professor Ramsay and Lord Rayleigh added argon, which they detected some three years ago, and now within the preceding two months krypton, neon, and metargon have been revealed, the last two discoveries having been made public within the past few days. According to *The Sun*, "all the new gases, krypton, neon, and metargon, possess the peculiar characteristics of argon inertness. Physical combinations of them, *i.e.*, mixtures, easily exist, but chemical action is entirely lacking as far as is known. It is not too much to say, how-

ever, that a new department of chemistry has just been opened. Its possibilities of knowledge are as yet only vaguely indicated, but already they are of vast scientific importance, and a series of fascinating revelations will soon be forthcoming."

The Laughing-Plant.—In the *Montreal Pharmaceutical Journal* for May is a description of the laughing-plant and its effects upon man. It grows in Arabia and derives its name from the effects produced by eating its seeds. The plant is of moderate size, with bright yellow flowers and soft velvety seed pods, each of which contains two or three seeds resembling small black beans. The natives of the district where the plant grows dry these seeds and reduce them to powder. A small dose of this powder has effects similar to those arising from the inhalation of laughing-gas. It causes the soberest person to dance, shout, and laugh with the boisterous excitement of a madman, and to rush about, cutting the most ridiculous capers for nearly an hour. At the expiration of this time exhaustion sets in, and the excited person falls asleep, to wake after several hours with no recollection of his antics.

Entente Cordiale.—The friendliness of the rivalry between the faculty of the old University Medical School and that of Bellevue Hospital Medical School has long been recognized. Still there are degrees of intimacy that pass the point of endurance, and when the members of these two rival faculties found themselves one year ago sitting in each other's laps in the professorial chairs of the combined institution, the limit seemed to have been reached and they flew from each other's presence like pith balls charged with opposite electricity. Now that their distinct paths have been marked out and lie in parallel lines at a sufficiently safe distance, we find them again falling on each other's necks, after the manner of imperial personages. When the Czar of all the Russias and the Emperor of Germany meet they signalize their friendship by appearing in each other's clothes. Behold! our medical friends adopting the same custom and presenting themselves in each other's domicile. Upon the opening of the fall session of the medical schools, Bellevue will be domiciled in the old buildings of the University faculty and the University faculty, under the designation of the Medical College of Cornell University, will have its temporary home in the old Bellevue buildings on the grounds of the hospital.—*Medical News.*

Cairo as a Resort.—The last winter season at Cairo was crowded enough to satisfy all the hotel keepers. About seventy-five hundred tourists, mostly English, Americans, and Germans, landed in Egypt between November and April. This number almost reaches that of the maximum year. Medically speaking, the season was a very healthy one, slightly marred by dengue in the autumn, while in the spring, as in many past years, influenza was imported by patients from Europe. The weather was decidedly cold throughout, being the exact reverse of the winter of 1896–97.—*The Lancet.*

An Influenza Baby.—While the influenza was at its height in New York some time ago, in a family where all were suffering with the disease a boy baby was born, and by unanimous consent was named Agrippa.—*American Hebrew.*

The Spanish Red Cross in Cuba.—*The Lancet* says that in the course of the first two years of the Cuban insurrection, members of the Spanish Red Cross Society nursed about fifteen thousand soldiers in the hospitals and some twenty-five thousand on the battlefield and in temporary shelters or ambulances. The question may be asked, how many Cubans this society has aided.

Bacteriology and its Triumphs.—In the theatre of the Royal Institution Dr. G. F. Klein, lecturer on physiology at St. Bartholomew's Hospital, recently gave the first of two lectures on achievements in bacteriology. In the course of his remarks the speaker quoted some remarkable statistics concerning the microbe and its manners. Its dimensions were so insignificant, he said, that a postage stamp would accommodate 500,000,000 of the typhoid species. Its fecundity was prodigious, so much so that if fifteen drops of water polluted with bacteria were allowed to fall into a cup of broth, the germ population would have increased in twenty-four hours to 80,000,000. So profound had been the researches of the scientists who made the matter a special study, that not only had the bacteria associated with various diseases been discovered, but their weight had been estimated. As an instance of this fact Dr. Klein said that it would take 122,000,000 specimens of bacillus typhi abdominalis to weigh one gram. So penetrating had been the studies of the bacteriologist that he could now detect one part of sewage, even if it were contained in as many as 500,000 parts of water.—*Sanitary Record.*

The Prejudice against the Tomato.—The tomato alarmists are at their old tricks again. Dr. Andrew Wilson, of London, says: "I have received several letters of late, reiterating a question I might well be tired of answering, 'Do tomatoes cause cancer?' But for the fact that one takes a pleasure in stamping one's foot on a misleading statement calculated to prejudice people against a vegetable food which is entirely healthful and safe, I should grow weary of asserting that not a jot or tittle of proof has ever been offered in support of the outrageous statement noted above. One might as well allege that cabbage causes cancer, for there would be no more proof of that assertion than there is proof to be had concerning the tomato myth. I can only repeat that the tomato is an excellent vegetable enough, and may be partaken of by those with whom it agrees, without any fear of its initiating any disease whatever."

Health Reports.—The following statistics concerning small-pox, yellow fever, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending July 16, 1898:

		Cases.	Deaths
Small-Pox—United States.			
New York, Dansville	May 2d to July 7th	3	
Geneva	May 21st to July 7th	6	
Ithaca	May 19th to July 7th	1	
Moravia	May 17th to July 7th	3	
Locke	July 7th	1	
Union Springs	May 18th to July 7th	2	
Westfield	April 28th to July 7th	3	
West Sparta	July 7th	2	
North Carolina, Reidsville	June 30th	1	
Ohio, Van Wert	July 8th	10	
Tennessee, Hamilton	May 1st to 31st	1	
Knox County	May 1st to 31st	21	
Norton	May 1st to 31st	9	
Small-Pox—Foreign.			
Belgium, Antwerp	June 4th to 11th	3	
England, London	June 11th to 18th	1	
London	June 18th to 25th	..	
Sunderland	June 11th to 18th	1	
India, Calcutta	May 21st	..	
Russia, Moscow	June 11th to 18th	6

RECENT EXPERIENCES IN MILITARY SURGERY AFTER THE BATTLE OF SANTIAGO.

BY LIEUT.-COL. N. SENN, M.D., U.S.V.,

CHIEF OF OPERATING STAFF WITH THE ARMY IN THE FIELD.

Wound Infection.—Military surgery differs in no essential respect from emergency surgery in civil practice. The surgeon in daily practice has learned long ago that every accidental wound must practically be regarded and treated as an infected wound. In this respect the military surgeon of to-day has the advantage over his colleague in civil practice in knowing that the small-calibre bullet inflicts wounds which *per se* are more often aseptic than septic. Our recent experience in Cuba has shown that the small jacketed bullet seldom carries with it into the tissues clothing or other infected substances. Most of the wounds of the soft tissues uncomplicated by visceral lesions, which in themselves would become a source of infection, healed by primary intention in a remarkably short time. If infection followed, it usually did so in the superficial portion of the wound in connection with the skin, and, what is more than suggestive, the wound of exit was more frequently affected than the wound of entrance. This can be readily explained from the larger size of the wound and more extensive laceration and tearing of the tissues. In many of the cases ideal healing of the wound did not occur, owing to a subsequent superficial suppuration of the wound. The deep tissues were seldom implicated in such cases. I have reason to believe that some of the compound fractures which are now suppurating had such a source of infection; that is, the extension of a superficial infection to the seat of fracture.

Two weeks have elapsed since the battle of Santiago was fought and we are now in a position to inquire more critically into the manner in which the wounds became infected. The many failures in protecting the more serious wounds against infection are attributable to three principal causes: 1. Inadequate supply of first dressings. 2. Faulty application of first dressing. 3. Unnecessary change of dressing. The medical officers with the regiments and in the field hospitals were hampered in their work by an insufficiency of proper dressing-material. The rapidity with which the invasion was planned and executed, the difficulties encountered in transporting the hospital supplies to the front, and the unexpected large number of wounded readily explain the lack of dressing-material where it was most needed. Most of the dressings were too small and not sufficiently secured to keep them in place during the transportation of the wounded from the front to the field hospitals. As a rule, not enough attention was paid to the immobilization of the injured part, an important element in securing rest for the wound and in guarding against displacement of the dressings. It is a source of regret that plaster-of-Paris dressings were not more frequently employed in the treatment of gunshot fractures of the extremities.

Another palpable evil in causing infection was the too common practice of unnecessary change of dressing. The transfer of patients from one surgeon to another could not be avoided. Patients brought from the first dressing-station to the field hospital usually were subjected to a change of dressing, and, when a few days later they reached the general hospital at Siboney, they had to undergo the same ordeal, and often not only once, but whenever they came into the hands of another surgeon. Patients not thus treated were dissatisfied, as the laymen are still laboring under the erroneous impression that the oftener a wound is dressed the quicker it will heal.

It is difficult to eradicate such a deep-rooted and time-honored belief and patients will continue to clamor for a change of dressing, and the good-natured and hard-working surgeons only too often yield to the unreasonable requests. The evil of meddlesome surgery has become very apparent during our brief Cuban campaign and has taught us an important lesson that must be heeded in the future. Our military surgeons must learn to realize the value and importance of the first-aid dressing. In all cases in which the first examination does not reveal the existence of complications which require subsequent operative treatment, the diagnosis tag should convey this important instruction: "Dressing not to be touched unless symptoms demand it." Such instruction is significant and must be followed to the letter by all surgeons in subsequent charge of the patient. I am satisfied more than ever of the necessity of including in the first-aid dressing-package an antiseptic powder. For years I have used for this purpose a combination of boric acid and salicylic acid, 4 to 1, with the most satisfactory results. I am also partial to sterile absorbent cotton in place of gauze for this particular purpose, as it constitutes a more perfect filter than the loose gauze. A teaspoonful of the powder mentioned dusted on the wound forms with the blood that escapes and the overlying cotton a firm crust which seals the wound hermetically. Should the primary dressing become saturated with blood, the same powder should be dusted over the wet dressing and an additional compress of cotton be added to the dressing. After the first dressing has been applied it should not be removed, except for good and substantial reasons. Much can be done in the after-treatment in the way of readjusting the bandage and in immobilizing the injured part, but the first dressing must remain unless local or general symptoms set in which would warrant its removal. Malaria and yellow fever, that crept in upon us so insidiously, are responsible for many unnecessary changes of dressing. The appearance of fever in a wounded man naturally leads to the suspicion that there is something wrong in the wound. Many dressings were changed on this ground; nothing abnormal was found in the wounds, and a day or two later the nature of the fever was recognized and the patients were either given quinine or were sent to the yellow-fever hospital, in accordance with the final diagnosis made. Every change of dressing, more especially in military practice, is attended by risk of infection, and must be scrupulously avoided unless local or general symptoms indicate the existence of complications

which demand surgical intervention. In writing the above it is not my intention to cast any reflection on the work of our surgeons; on the contrary, I willingly bear witness to the ability, faithfulness, and unselfishness with which they have done their duty. A better and more conscientious group of medical officers it would be difficult to select anywhere. The results on the whole are excellent, but I am hopeful that they can be improved in the future by placing more stress upon the value and importance of the first dressing, and I wish to repeat again and in the most forcible way the language of the late Professor von Nussbaum: "The fate of the wounded rests in the hands of the one who applies the first dressing." If this be true in civil practice, its meaning cannot be misinterpreted in military surgery.

Effects of Bullets on the Soft Tissues.—In recent cases the small tubular wound made by the Mauser bullet was surrounded by a narrow zone of contused tissue and the wound space itself filled either with liquid or with coagulated blood. A few days later the wound itself was found surrounded by an area of suggillation which varied in extent according to the nature of the injured tissues and the amount of extravasation. In cases in which the bullet passed through the tissues some distance and not far from the surface of the skin, the location and direction of the wound canal were indicated by a discoloration of the skin a few days after the injury occurred. In a number of cases of aseptic wounds, in which the bullet had lodged in the tissues and was removed a week or ten days later, I had an opportunity to study the remote effect of the injury on the tissues. In all cases the swelling of the tissues at this time had nearly or entirely obliterated the tubular wound, the location of which was indicated by a dark discoloration, parenchymatous extravasation, remains of fluid or coagulated blood, and a limited area of œdema and infiltration. These conditions served as a useful guide in following the course of the bullet. The bullet itself was usually found loose in a small cavity filled with liquid blood or bloody serum, while a more extensive zone of infiltration indicated the early stage of encapsulation. I have no further doubt that the new bullet will become encapsulated and remain harmless in the tissues as readily or more so than the old-fashioned leaden bullet. In isolated cases late suppuration at the seat of the bullet resulted in the formation of a circumscribed abscess, a complication which aided the surgeon in locating, finding, and removing the missile. It was a surprise to us all to find that in more than ten per cent. of all the wounded the bullet was lodged in the tissues, a vastly greater number than we had any reason to expect. The cause for this became apparent when we began to study the condition of the bullets recovered. A large proportion of the bullets recovered were found deformed, showing that they were deflected bullets which had struck a hard object, or had passed through a resisting medium before they reached the object for which they were intended. The ground upon which the battle was fought is stony and covered with trees and thick underbrush, furnishing the most favorable conditions for deflection of the missiles. Some of the firing was done at a great distance, so that occasionally a spent ball was found in the soft tissues without injury of the bone. One of these bullets was a nickel-encased Mauser projectile, natural size, the jacket perfect, that was removed from the leg about four inches above the ankle-joint. It had entered the calf of the leg below the popliteal space and never touched the bone. I have another bullet of the same kind, the point of which is flattened and much rounded, which was removed from the head of the tibia. This bullet was probably fired from a great distance, and the deformity was produced by the bone. Another was a nickel-clad bullet very much deformed. It was found lodged in the deep tissues of the thigh, about two inches from the wound of entrance, slightly overlapping the femur near the middle of the shaft. The bullet evidently struck a stone behind its point and was deflected before it entered the tissues. It was much flattened and curved. The convex side and point of the bullet and jacket were perfect, the lead being exposed between the edges of the case.

The Value of the X-Ray in Military Practice.—The value of the probe as a diagnostic instrument in locating bullets has in modern military service been almost entirely superseded by dissection and the employment of the *x*-ray. If from the nature of the injury and the symptoms presented the bullet is located in a part of the body readily and safely accessible to the knife, and it is deemed advisable and expedient to remove it, this can often be done more expeditiously and with a greater degree of certainty by enlarging the track made by the bullet than by relying on the probe in finding and on the forceps in extracting the bullet. If, as is often the case, the whereabouts of the bullet is not known, its presence and exact location can by the use of the *x*-ray be determined without any pain or any additional risks to the patient. All of the bullets removed on board the hospital ship *Relief* were located in this manner. Dr. Gray, an expert in skiagraphy, who has charge of the scientific work of the floating hospital, has been of the greatest service to the surgeons in enabling them to locate bullets and in guiding them as to the advisability of undertaking an operation for their removal. His large collection of skiagraph pictures will also furnish a flood of new light on the effect of the small-calibre bullet on the different bones of the body. Dr. Gray's work will constitute an essential and enduring cornerstone of a much-needed modern work on military surgery. The skiagraph has enabled us to diagnosticate the existence or absence of fractures in a number of doubtful cases in which we had to depend exclusively on this resource. In fractures in close proximity to large joints the *x*-ray has been of the greatest value in ascertaining whether or not the fracture extended into the joint. In one case of gunshot wound at the base of the thigh, in which the bullet passed in the direction of the trochanteric portion of the femur, opinions were at variance concerning the extent of injury to the bone; some of the surgeons made a diagnosis of fracture, while others contended that there was no fracture, but believed that the bullet had made a deep groove in the anterior portion of the bone and had possibly opened the capsule of the joint at the same time. The *x*-ray picture clearly demonstrated the absence of fracture and the existence of a deep furrow with numerous fragments on each side. The *x*-ray apparatus also proved of the greatest practical utility in showing the displacement of fragments in gunshot fractures of the long bones, and enabled the surgeons to resort to timely measures to prevent vicious union. The fluoroscope has greatly added to the practical value of skiagraphy. In the light of our recent experience the *x*-ray has become an indispensable diagnostic resource to the military surgeon in active service, and the suggestion that the chief surgeon of every army corps should be supplied with a portable apparatus and an expert to use it must be considered a timely and an urgent one.

The Wounded of the Battle of Santiago.—It will be of interest to the profession to know something definite of the nature of the wounds and of their more remote results on the victims of Spanish bullets in the battle of Santiago. Two weeks have passed away since the battle. A considerable number of the wounded have died since and many have left for the United States on the *Olivette*, *Solace*, and transport ships.

From among the one hundred and twenty-seven wounded now on the way to their homes on the hospital ship *Relief*, I have selected a number of cases of more than usual interest, for the purpose of studying the effects of the small-calibre bullet, immediate and remote, on the different organs and regions of the body. It is my intention to give the course of the bullets by marking on the diagrams accompanying the report of each case the wound of entrance and exit. A study of the diagrams will show that deflection of the bullet in the body is exceptional; as a rule, the wound canal was in a perfectly straight line from one wound to the other. By following the track of the bullet it is not difficult to determine the organ or organs implicated in the injury. I shall classify the cases so as to embrace gunshot wounds of, 1, the head; 2, the neck; 3, the spine; 4, the chest; 5, the abdomen; 6, the extremities.

Gunshot Wounds of the Head.—To my own knowledge a number of sufferers from gunshot wounds of the head who survived long enough to be transported to the general hospital at Siboney died within twelve days after the receipt of the injury. In all of the cases intracranial infection was the immediate cause of death. Encephalitis and leptomeningitis constituted the fatal complications. The beginning of the intracranial inflammation was always announced by cerebral hernia, which in size was proportionate to the extent and intensity of the inflammatory process. The surgical treatment resorted to in most cases proved powerless in limiting the infection. If these cases had been studied with a little more care during life and if post-mortem examinations had been made more frequently, valuable material could have been obtained for the advancement of the as yet imperfectly developed science of cerebral localization.

Case I.—Fred. Shockley, company D, tenth cavalry, wounded July 2d. When the injury was received the patient was lying on his abdomen with chest and head extended, at the base of the ridge occupied by the enemy, which position readily explains the unusual course of the bullet. The bullet struck the occipital bone at a tangent, producing a comminuting fracture with depression; it made a deep groove in the back of the neck and then entered the body on a level with the first rib to the left of the seventh cervical vertebra, passed through the chest, and escaped in front through the second intercostal space, a little to the left of the mammary line. Soon after the injury was received he coughed up a small quantity of blood; no hemorrhage since or any indications of hæmothorax, pneumonia, or pleuritis. The chest wounds healed by primary intention. At first he had convulsions for a few moments; no loss of consciousness, but clonic spasms of both arms. At present intellect is unimpaired; has some headache and a sensation of throbbing in the head; some impairment of motion and sensation of right leg and complete loss of motion of toes of right foot. Had some pain in eyes and slight dimness of vision.

Case II.—Patrick Ward, company I, third cavalry, admitted from hospital at Siboney to hospital ship *Relief*, July 11th. Injury probably received in the same manner as in Case I. A large defect in the occipital bone marked the wound of entrance and exit in the skull; the opening was enlarged by operation. The linear wound between and extending as far as the last cervical vertebra was undoubtedly made in following and removing the bullet. A cerebral hernia projects from the opening, and a deep-seated cerebral abscess was recently discovered, opened, and drained. In part the hernia is covered by skin. Both parietal bones are the seat of a comminuted fracture. Mental faculties not impaired; no focal symptoms. The patient is losing strength rapidly and will soon succumb to the intracranial lesion.

Case III.—James Russel, company A, thirteenth infantry, was wounded July 1st. When he was brought on board the *Relief*, a cerebral hernia about the size of a hen's egg was found over the sagittal suture, an inch in front of the occipital protuberance. The opening was evidently the wound of entrance, and by operation has been connected with the wound of exit by a channel an inch in length and half as wide. The hernia occupied the wound of exit. A number of loose fragments of bone have been removed at different times. There is marked hemiplegia on the left side; the forearm is strongly flexed and in close contact with the chest. Sensation not diminished; speech clear but ideas confused; pupils react to light; incontinence of urine; extensive decubitus over sacrum; temperature, 100.5° F.; pulse and respiration normal.

Case IV.—B. C. Parker, company C, fourth infantry, was wounded July 1st. The bullet entered the left temporal region, comminuting the bone in that region extensively, and escaped over the left frontal eminence. The cranial defect was increased by the removal of a number of loose fragments. There has been quite a profuse sero-purulent discharge from the wound. The only focal symptom consists of a prickling sensation of the right foot or chest when the wound is being dressed. Mind clear most of the time; occasionally slight confusion and wandering. The absence of cerebral hernia in this case is the surest indication that the infection is local.

Gunshot Wounds of the Neck.—Case V.—Lieut. Albert Scott, company C, thirteenth infantry, on July 1st, while standing with his company at the foot of a hill during the advance on Santiago, received a wound in the neck. The bullet entered the neck on the right side, just below the inferior maxillary bone, an inch in front of the angle of the jaw. The wound of entrance is a clean-cut hole about the size of a lead pencil. The course of the bullet was backward and slightly downward, emerging at the back of the neck on a level with and to the left of the fifth cervical vertebra. At the moment the injury was inflicted he felt no pain in the wound, but he experienced a sensation as if he had been grasped by the wrists and thrown violently to the ground. The wound of exit is of the same size and appearance as the wound of entrance; very slight hemorrhage. A few minutes after receiving the injury he was carried from the firing line by members of his company and was soon transported to the first division hospital, where he remained for ten days, after which he was removed in an ambulance to the hospital at Siboney, a distance of seven miles over a very rough road, and a day later was transferred to the *Relief*. He first became aware of the existence of the wound on the way from the field to the hospital. At the time he came on board the hospital ship he was voiceless and made constant efforts to clear the bronchial tubes of mucus. Complete paralysis of right arm and leg and partial loss of power in left arm and leg; respiration normal but an almost constant spasmodic cough; no control over sphincters; involuntary passages from both bladder and bowels; great debility and profuse sweating. Complains of pain all over the body. Morphine and atropine to subdue pain. A radiograph taken by Dr. Gray shows an injury of one of the cervical vertebræ, probably the fifth. Injury seems to be to the left of the body of the bone. Has received no treatment other than complete rest and a nightly anodyne as noted above, which secures a good night's sleep and markedly diminishes the sweating. Has regained control of the sphincters and is able to use bed pan and urinal. July 19th—during the past six days there has been a decided improvement in the general condition of the patient. He is bright in appearance; he can articulate more distinctly and there is a decided return of power in the right leg. The

right hand is still absolutely powerless, but the grip of the left hand is decidedly stronger. Appetite and circulation good. July 21st, improvement in general condition still continues. The external wound healed by primary intention and the scar can be seen only by making a careful inspection. Trional and sulphonal have been substituted for the morphine.

Case VI.—Oscar C. Buck, company F, second infantry, was shot by a sharpshooter hiding in a tree, July 1st. The bullet passed through the neck, from side to side. The first and only evidence that the patient had that he was injured was bleeding from the throat; the hemorrhage at first was quite profuse. Stiffness of the neck and pain on movement have been the only symptoms complained of since. The bullet entered over the sterno-cleido-mastoid muscle on the left side, about two and a half inches from the mastoid process. The wound of entrance was circular and very small; the wound of exit on the same level and about half an inch nearer the spine. Three days later a small superficial abscess formed in the wound of exit, which was evacuated by dilating the wound. Both wounds were perfectly healed July 20th. Judging from the course of the bullet, it is difficult to understand how the principal nerves and large vessels of the neck escaped injury. This is one of those cases that require careful watching, as a traumatic aneurism may develop in the event the bullet injured the external tunics of either carotid artery.

Case VII.—Charles F. Flickinger, company C, fourth infantry, was wounded July 1st, while lying down. The bullet entered the left posterior cervical triangle on a level with the spinous process of the fifth cervical vertebra, midway between the spine and the posterior border of the sterno-cleido-mastoid muscle, and emerged opposite the spinous process of the seventh dorsal vertebra, and equidistant from that point and the posterior border of the scapula. The patient complains of severe pains in the shoulders on attempting to move, but is free from any symptoms that would indicate any injury to the spinal cord. He was within one hundred yards of the enemy when he was wounded.

Gunshot Wounds of the Spine.—All who received gunshot wounds of the spine in which the cord was seriously damaged have died or will die in the near future. The immediate cause of death in such cases is either a septic leptomeningitis or sepsis and exhaustion from decubitus. Death from the first-named cause takes place early, as the result of infection of the wound and extension of the inflammation at the seat of the visceral injury along the meninges and surface of the spinal cord. The first case of this kind I saw at El Caney, a few days after the battle of Santiago. The patient was a Spanish prisoner. I found him lying on the bare stone floor of the village church. The bullet had entered over the centre of the spine at the junction of the dorsal with the lumbar vertebræ, its course apparently being directly forward. Complete paraplegia below the seat of injury. Bladder distended, reaching nearly the level of the umbilicus; incontinence of urine. The neck, trunk above the wound, and upper extremities rigid; fever; pulse rapid and small; countenance extremely pale. The wound was protected by a small, dirty dressing, and was suppurating. I doubt not the patient died in less than twenty-four hours after I saw him. Wounds of the spine without injury to the cord frequently gave rise to temporary paralysis, varying greatly in degree and duration.

Case VIII.—George Kelly, company C, seventeenth infantry, was shot July 1st, while lying in a prone position. The bullet, which was fired from a blockhouse on the summit of a hill, at a distance of about six hundred yards, entered the body at a point a little below and at the middle of the right ilium, and emerged from the opposite side about three inches below the crest of the ilium. The patient asserts that he suffered intense pain immediately after he was shot, and that he is now free from pain except when he attempts to walk. The pain thus caused he refers to the sacro-coccygeal articulation. The wounds are healed, and the absence of paralysis is the best evidence that the contents of the spinal cord escaped injury, although the bullet must have passed transversely through the first sacral vertebra.

Case IX.—John Robinson, company C, twenty-fourth infantry. The bullet entered the supraspinous fossa of the left scapula and escaped from the right lumbar region, having perforated in its long course the lung, spinal cord, diaphragm, and liver. Wounds healed in ten days. Expectoration bloody. Complete paraplegia. Beginning extensive decubitus over sacrum and spinous processes.

Case X.—Otto Derr, company A, twenty-first infantry, was wounded July 2d. Bullet passed through the chest from side to side, from the postaxillary line on the right side to a corresponding point on the opposite side on a level with the seventh intercostal space. Complete paralysis of motion and sensation below the seat of spinal injury. The wound healed, but life was threatened at the time from a commencing septic decubitus.

Case XI.—Lewis M. Carlisle, company K, seventy-first New York volunteers, was hit by a shrapnel in the back on a level with the third lumbar vertebra, the spinous and left lateral processes of the same being shattered. The missile was removed as soon as the patient reached the division hospital. As profuse suppuration set in and continued, the patient was anæsthetized on the 18th and a number of fragments of bone were removed. A large abscess cavity in the right lumbar region communicated with the wound. The cavity was drained by making a counter-opening in line with Simon's incision. Impaired sensation in the right leg was the most important focal symptom in this case.

Case XII.—Charles J. Reardon, company C, sixteenth infantry, was wounded by a fragment of shrapnel which struck him as he lay on his back with his shoulders raised, ready to fire. The wound was directly over the spine, on a level with the fourth dorsal vertebra; the missile evidently opened the spinal canal and injured its contents. The foreign body remains embedded in the tissues; its location so far has not been determined. Paraplegia is complete below the level of the umbilicus. On the 18th the patient was still alive, but an extensive moist decubitus will become the direct cause of death in the course of a few days.

Gunshot Wounds of the Chest.—It is well known that during the war of the rebellion men had a better chance for life when the bullet passed through the chest than when the chest was opened and the ball remained. The same remains true now, although not to the same extent, as the small-calibre bullet is less likely to carry with it into the chest clothing or other infectious material. The number of those with chest wounds who have lived long enough to reach the hospital on the coast is astonishing, and, what is still more surprising, is the fact that unless the hemorrhage was severe the symptoms were mild, some of the patients being confined to bed only for a few days. All of these cases were treated on the expectant plan—that is, by dressing the external wound or wounds; in no instance was the pleural cavity opened for the purpose of arresting the hemorrhage.

Case XIII.—William A. Cooper, company A, tenth cavalry, was wounded July 1st. The bullet entered an inch below the left nipple and escaped from the

body an inch below the costal arch in the mammary line. It is questionable whether the bullet opened either the pleural or the peritoneal cavity, as the injury was not followed by any symptoms referable to visceral wounds of the chest or abdomen, although the course of the bullet was such as to give rise to the suspicion that either or both of these cavities might have been invaded.

Case XIV.—Edward O'Flaherty, company C, sixteenth infantry, was wounded, July 2d, by a ball, forty-five calibre, from a bursting shrapnel. The projectile entered below the angle of the right scapula, passed through the lung, diaphragm, liver, and lodged beneath the skin in front between the seventh and eighth ribs. Bloody expectorations for some time and slight elevation of temperature. July 12th, temperature normal. July 21st, patient suffers but little inconvenience from his wound. No peritoneal or pleural effusion. General condition promises an early and complete recovery.

Case XV.—John B. Senica, company G, twenty-second infantry, was wounded, July 1st, by a bullet which entered his back just below the angle of the left scapula, passed upward through the lung, neck, and jaw, and emerged through the alveolar process of the right bicuspid tooth, cutting the tongue slightly. All the wounds healed in a short time by primary intention. Hæmoptysis profuse immediately after he was shot, and slight for the following few days. Left arm at first nearly powerless, with desquamation of the skin of the hand. Function of the arm returning gradually. In three weeks the patient was able to sit up for a short time each day. Physical examination of the chest at this time revealed nothing abnormal.

Case XVI.—Winslow Clark, company G, first volunteer cavalry, was wounded, July 1st, by a bullet which entered the chest after perforating the left scapula through the infraspinous fossa, three inches above the angle and an inch from the spinal border. No wound of exit. The probable course of the bullet was downward and forward. Some hæmoptysis and fever. No vomiting of blood. The hæmothorax was quite extensive, and was relieved by tapping a week after the injury. He is now (July 22d) convalescing rapidly.

Case XVII.—Arthur Fairbrother, company C, third cavalry, sustained a perforating gunshot wound of the chest, July 1st. The bullet entered the chest just below the middle of the right clavicle. No wound of exit. Hæmoptysis rather profuse, followed by hæmothorax. Has had fever off and on, probably malarial. Patient was admitted to the *Relief*, July 15th. Wound not completely closed. On coughing, dark fluid blood escapes. Nearly the entire pleural cavity filled with blood. Two days later three pints of dark fluid blood were removed by tapping and siphonage. Sputum at this time still bloody. July 22d, patient much improved. No signs of empyema. Hæmothorax diminished, but may require a second tapping.

Case XVIII.—Scanlon, company K, third cavalry, was wounded on the second day of the battle of Santiago. The ball entered the chest through the third rib, midclavicular line, on the right side, passed downward and backward, and escaped in the gluteal region on the same side, after perforating the ilium. The ball must have passed through the lung, diaphragm, and liver. Hæmoptysis slight, but distressing nausea, vomiting, and pain. Admitted to the hospital ship *Relief*, July 15th. At that time he had a temperature ranging between 100°–102° F., vomiting, diarrhœa, and rapid emaciation. Great pain over the liver and along the ascending colon. Hæmothorax and marked swelling in the region of the liver and abdominal cavity on the right side. Examination of the urine negative. Owing to the great debility and pronounced anæmia, it was not deemed advisable to resort to laparotomy.

Case XIX.—Henry Mitchell, company C, seventh infantry, was wounded July 1st. The bullet entered over the right acromion process, passed through the apices of both lungs, and escaped through the second intercostal space above the right nipple. No hæmoptysis at any time, dry cough, and a moderate hæmothorax on the right side. Has suffered from quotidian form of malarial fever, which is yielding to quinine. A speedy and complete recovery is expected.

Case XX.—Lieut. John Robertson, company G, sixth infantry, received a gunshot wound of the upper third of the right thigh at about three o'clock July 1st. The profuse hemorrhage was partly controlled by an improvised tourniquet applied by an officer of the line. He was carried to the rear by men of his company, and while thus conveyed he was shot in the left breast, the bullet entering just below the left nipple and passing through the chest in an antero-posterior direction. He was wounded a third time, the bullet grazing the inner side of the left knee. The first dressing was applied in the first division hospital. The fracture of the thigh was dressed by the use of a long splint. From here he was sent, on the 9th of July, to the third division hospital, and two days later was brought on board the *Relief*. At this time both chest wounds were healed. The thigh wounds remained aseptic. A radiograph showed great displacement of the fragments by overlapping. The fracture was then treated by confining the limb upon a double inclined plane, consisting of a hollow posterior splint made of the sheath of the leaf of the cocoa palm, to which was added an anterior thigh splint of wire gauze. After being dressed the limb was suspended in a sling. No pulmonary or pleuritic complications.

Case XXI.—Henry T. Darby, company D, thirteenth infantry, received a perforating gunshot wound of the chest, July 1st. The ball entered on the right side above the angle and at the outer border of the right scapula, passed through the chest, and escaped through the fourth intercostal space in front on the opposite side, two inches outside of the mammary line. When the patient came on board the *Relief*, July 9th, he complained of great difficulty of breathing; he was pale and greatly prostrated; temperature, 102° F. The physical signs indicated the presence of a copious pleuritic effusion on the left side. The chest was opened by an incision through the sixth intercostal space in the axillary line, July 11th. About three pints of fluid blood escaped. Gauze drainage. The lung expanded rapidly and the patient commenced to improve.

No further doubt remains in regard to the difference in the mortality of gunshot wounds inflicted with the large and the small calibre bullets. The cases related above appear to prove that the danger incident to gunshot wounds of the chest made by the small projectiles consists in complicating injuries involving the heart and large blood-vessels, and that in the absence of such injuries the progress is favorable. It seems that empyema is a rare remote result of such injuries. Rib resection and free incision and drainage of the chest must be reserved for cases in which a positive diagnosis of empyema can be made. The safest and best treatment for hæmothorax requiring operative interference is tapping and evacuation by siphonage.

Gunshot Wounds of the Abdomen. — Our recent experience in Cuba has more than ever confirmed my convictions that not infrequently cases of penetrating gunshot wounds of the abdomen will recover without active surgical interference. For years I have maintained, as the result of clinical experience and experiments on the cadaver, that a bullet may pass through the abdomen on a level with and above the umbilicus in an

antero-posterior direction without producing visceral injuries demanding operative intervention. Elsewhere the results of my experience and experimentation concerning such injuries have been published. If the bullet traverses the small-intestine area, it is more than probable that from one to fourteen perforations will be found. Four laparotomies for perforating gunshot wounds of the abdomen were performed at the first division hospital, the only cases to my knowledge during the Cuban campaign. All of the patients died. This unfavorable experience should not deter surgeons from performing the operation in the future in cases in which from the course taken it is reasonable to assume that the bullet has made visceral injuries which would be sure to destroy life without surgical interference. In other cases the employment of diagnostic tests for the purpose of determining the existence or absence of intestinal perforations will enable the surgeon to determine what course to pursue. Abdominal section is always justifiable in cases of internal hemorrhage sufficient in amount to threaten life. A number of gunshot wounds of the abdomen have been related in connection with gunshot injuries of the neck and chest, in which the cavities of the chest and abdomen and their contents were implicated at the same time, and which are on the way to recovery without laparotomy having been performed. I have seen a number of cases of perforating wounds of the abdomen in the first and third division hospitals that were on a fair way to recovery without operation, before they were sent home on transports. In most of these instances the bullet wounds were either in the umbilical region or in one of the iliac fossæ. The following case presents features of more than usual clinical and surgical interest:

Case XXII.—J. F. Taylor, company D, tenth cavalry, was wounded July 2d. At the time the injury was received he was in the ventral prone position. The bullet entered the left shoulder in the infraspinatus fossa of the scapula, and passed downward and inward and lodged under the skin in the median line, two inches above the umbilicus. Hæmoptysis considerable during the first day, when it gradually subsided. He complained of great pain and tenderness in the right side of the abdomen. No vomiting or symptoms of more than a circumscribed peritonitis. An abscess formed in the abdominal wall, which was opened July 20th, and the bullet was removed. From this time on the patient improved rapidly.

Gunshot Wounds of the Extremities.—It is a source of gratification to know that few primary amputations were made for gunshot injury of the extremities. All of the surgeons realized the importance of conservative measures in the treatment of such injuries, and limited amputations to cases in which the condition of the soft tissues precluded any other course. A number of secondary amputations became necessary to save life in cases of infected compound fractures complicated with injury and infection of the adjacent joint. Two cases of traumatic aneurism are now on board the *Relief*—one an aneurismal varix, the other an aneurism of the femoral artery.

Case XXIII.—Captain Mosher, company G, twenty-second infantry, received a bullet wound July 1st, during the advance on Santiago. Those who saw the patient first assert that the hemorrhage was severe and that he lost consciousness. He was removed to the first division hospital and transferred, July 10th, to the third division hospital, and the following day he was brought on board the *Relief*. I examined the patient at the front four days after the injury, and confirmed the diagnosis made by the attending surgeons, who had recognized the anatomical nature of the aneurism. The wounds healed by primary intention in less than two weeks. One wound was in the middle of Scarpa's triangle, and the other at the level and one inch posterior to the great trochanter on the same side. From the fact that there is shown by the radiograph a piece of the jacket of a bullet in the right popliteal space, it is probable that he was wounded by a plunging fire and that the bullet inflicted the latter wound after emerging from the wound in Scarpa's triangle. The wound in the popliteal space is suppurating. The patient is very anæmic and weak. In the triangle directly under the wound there is a pulsating swelling in the direction of the femoral vein, which extends to Poupart's ligament. Fremitus and the characteristic bruit extend a considerable distance above and below the communicating opening between the artery and vein. The treatment consists in rest and tonics. The general health of thepatient is improving, but there is no change in the local condition. The mental condition, much impaired since the injury, is gradually improving.

Case XXIV.—John J. Welch, company M, second Massachusetts volunteers, was wounded July 1st. The bullet entered Scarpa's triangle three inches below Poupart's ligament, directly over the femoral artery, and escaped at a point corresponding with the gluteal crease and to the outside of the femur on the same side. Not much hemorrhage. A well-marked aneurism developed, presenting all of the physical signs characteristic of such a pathological condition. The swelling is somewhat elongated, a little larger than a hen's egg, and has not increased in size since the patient came on board the hospital ship. The leg is somewhat œdematous and painful.

A number of gunshot fractures of the thigh and leg have become infected, and are now being treated by establishing free tubular drainage and resorting to frequent or continuous antiseptic irrigation. Owing to the want of reliable plaster of Paris, we had to resort to various kinds of splints, simple and double inclined plane, in effecting immobilization. The sheath of the leaf of the cocoa palm has served as an excellent material for this purpose. There is every prospect that most of these cases will ultimately recover with useful limbs.

In conclusion, I desire to thank Acting Assistant Surgeons Metcalfe, Torney, Greenleaf, Morrow, Hartsock, and Schultze, for valuable assistance in preparing this communication.

On Board the Hospital Ship "Relief,"
July 22, 1898.

THE ETIOLOGY OF GASTRIC ULCER, AND AN OUTLINE OF ITS THERAPEUTICS.

By A. A. BERG, M.D.,
new york.

Of late years the diseased conditions of the stomach have received more than their quota of attention from the specialist, the surgeon, and the general practitioner; and justly so, for, although the recent excision by Schlatter of the entire organ has conclusively shown that its presence is not vital, yet its importance to the general well being of the individual is of the highest; and in its diseased state the comfort, the economy, and the nutrition of the patient suffer greatly.

Its normal chemical and mechanical functions are at the present day fairly well understood, and the knowledge we have of its working in health has enabled us to carry out a rational form of therapeusis when it is diseased; but while our attention has been directed to the chemistry and functions of the stomach in health and disease, little thought has been given to the prevention of gastric affections, and in these days of preventive medicine more care should be given to

the avoidance of those causes and factors which result in pathological states. This can be accomplished only when we are fully aware of the pathogenesis of the disease we wish to prevent.

It is with this idea in view that I have been led to consider the etiology of gastric ulceration. The subject has been recently much discussed abroad by both the physician and the surgeon; and owing to the highly meritorious labors of such men as Leube, Carle, Mikulicz, and Doyen we have come to consider gastric ulcer in a new light. It is no longer to be classed as entirely in the domain of the internal medical diseases, and the recent statistics of Doyen, Mikulicz, and others prove that much can be done for those cases of ulcer which have resisted all attempts of diet and drugs to bring about healing.

Our earliest works on medicine took notice of what we understand to-day as idiopathic or primary gastric ulcer, and from these earliest times up to the present day succeeding generations of medical men have attempted to explain the pathogenesis of this condition; so that our literature abounds with theories as to the cause of this primary ulceration of the stomach wall. Some of them can be fitly applied to a class of the cases; others have not stood the test of time at all, and have been consequently abandoned for more rational theories.

Let me rapidly review some of the more prominent of the previous explanations. The theories which have received greatest support up to the present day may be classed under the following heads: Due, first, to changes in the blood and vascular system; second, to changes in the gastric juice; third, to disturbances of the nervous system, including the spinal cord.

As regards the changes in the blood, they may be considered under two distinct headings: (*a*) changes in the amount of the blood; (*b*) changes in the chemical relations of the blood.

It was shown experimentally by Quincke and Detwyler that when acute anæmia was induced in an animal by venesection an artificially produced lesion of the gastric mucosa did not heal; whereas Griffin and Vassale have demonstrated that artificially produced ulcers of the gastric mucosa in healthy animals healed very quickly. The only conclusion we can draw from these experiments is that when the nutrition is poor, as must be the case in a severe acute anæmia, healing, if it occurs at all, must necessarily be a slow process. These experimenters do not say whether such lesions healed if the animals experimented upon were allowed to regain their normal condition.

As regards the importance of chemical changes in the blood, much has been said and written. To Pavy belongs the credit of first suggesting the importance of changes in the chemical reaction of the blood as being of causative relation to the pathogenesis of gastric ulcer.

In the healthy individual the normal gastric juice is prevented from digesting the gastric mucosa by its neutralization with the alkaline blood, as soon as it penetrates the mucous membrane; such digestion is possible, according to this idea, only when one of three conditions attains: (*a*) hyperacidity of the gastric juice, and hence its neutralization by the alkalinity of the blood being no longer possible; (*b*) when the circulation in the stomach wall is so poor that neutralization of the gastric juice is not possible by the small amount of blood circulating in its walls; (*c*) when the alkalinity of the blood itself has been diminished.

The first of these conditions, viz., such hyperacidity of the gastric juice that its neutralization by the blood is not possible, can scarcely be referred to as a causative factor in the production of gastric ulcer; because, firstly, not all cases of gastric ulcer are attended with hyperacidity[1]—thus, out of eighteen cases in Eichhorst's clinic, eight had normal HCl, four hyperacidity, three hypacidity, and three anacidity; secondly, if such neutralization were impossible, why does not the digestion extend to the entire gastric wall?

This latter objection would apply equally well to the other two conditions just referred to, viz., diminished alkalinity of the blood or poor gastric-wall circulation. At this point we can also mention the importance of changes in the vascular system and their etiological influence in the production of gastric ulcer.

Pavy showed that ulcer could be produced by ligation of the vessels of the stomach wall; Miller, by ligation of the gastric and portal veins; and Panum, by artificial embolism of the gastric vessels. Such experiments merely indicate a local gangrene of the parts supplied by the affected vessels, and when such disease exists in the human body we would expect a lesion such as was produced by these experimenters. But such an ulcer is evidently not what we mean by primary gastric ulcer, nor are such diseases of the vascular system demonstrable in the vast majority of cases of gastric ulceration. Then, again, the theory of Klebs, that gastric ulcers are due to disturbances of circulation attendant upon spasm of the blood-vessels, is hardly tenable; for such spasm would have to be of long duration and localized to a small area of stomach wall. Again, the opinion of Axel Key, that ulcers are due to a circulatory disturbance following a spastic condition of the muscularis, is non-applicable, for the same reason. The local necroses of the mucosa that follow upon ecchymoses into its substance will explain only those cases in which a hemorrhage into the mucous membrane can be distinctly proved. But this condition, again, can hardly be classified along with the primary ulcers of the stomach, for they are of entirely different causation, and entirely different in their clinical behavior.

The importance of disturbances of the nervous system in their etiological relation to gastric ulcers is gaining recognition by many. Koch and Ewald, Schiff and Ebstein, have shown that section of the spinal cord, injuries to the anterior horns of the spinal cord, and section of the medulla are followed by gastric hemorrhage and ulceration, and hence infer that spinal-cord lesions are often factors in gastric ulceration. But such spinal-cord disease has not as yet been demonstrated in the human being as attended with gastric ulcer. Micro-organisms have also been assigned as a cause of gastric ulcer. Thus Boettcher isolated colonies of micrococci from the surface of the ulcers; Letulle isolated streptococci, which he thinks produce ulceration in one of two ways—either directly, when they are deposited on the mucous membrane; or when they are brought by the blood as emboli to the stomach from inflammations in distant organs.

From this rapid survey of the theories heretofore advanced as the causative factors in the production of the pathological condition under consideration, we see at once, first, that gastric ulcer has been considered as a unique condition, bearing no similarity or relation to ulceration in other parts of the body; but as long ago as 1859 W. Brinton, in his treatise on gastric diseases, said: "We have no more right to talk of the ulcer of the stomach than of the ulcer of the leg;" and, while he does not explain the true pathogenesis of gastric ulceration, we are commencing to see the full truth of his remark; secondly, that no one theory will explain the etiology of all cases of strictly primary gastric ulcer; and thirdly, that the clinical history of these cases is ascribed to the presence of the ulcer. But why some cases of ulceration of the stomach are

[1] Jaworsky and Korczynski (Zeitsch. f. klin. Med., Bd. xii.) and Riegel (Deut. med. Wochensch., 1886) asserted that all cases of gastric ulcer were attended with hyperacidity.

never attended with any or at the most only slight clinical manifestations is not accounted for.

Before I go on to state what I consider to be the real pathogenesis of gastric ulcer, let me review the site of these ulcers in the stomach wall, the age at which they are most frequently met with, and the geographical distribution of the disease.

In the first place, many facts tend to show its close relation to a diminished functional activity, viz., (*a*) its greater predominance in the female sex; (*b*) its very frequent association with anæmic and tuberculous conditions; (*c*) its absence in regions where the people are sturdy and vigorous—for example, the Alps, Russia; and (*d*) its presence in many of those who follow a sedentary life—for example, shoemakers, weavers, tailors, etc.

As regards the site of gastric ulcer, we find here a striking fact, viz., that the ulcer is situated most commonly on the posterior wall of the pyloric portion at or near the lesser curvature. Surely this would point to the pylorus as the offending member in the production of the majority of these cases, for there is certainly no other reason for the site of the ulceration being at this part.

Let us now consider the physiology of the stomach as a muscular organ. When food is introduced into the stomach, the pylorus closes and the stomach becomes a closed pouch in which the food is churned thoroughly with the gastric juice. This churning-process goes on until the requisite changes have been wrought in the food, when it is ready to be propelled onward into the duodenum. The plyorus now opens and the stomach resolves itself into two distinct parts: (*a*) the fundus, which continues to act as a churn; (*b*) the pyloric end, which becomes a pump in its action and pumps the chyme into the duodenum.

This physiological fact is again very important to bear in mind in considering the pathogenesis of gastric ulcer. In the normal stomach we find that about seven hours after eating it has emptied itself, and upon the completeness with which this takes place depends to a great degree its condition of health or disease.

The stomach may fail to empty itself from one of two causes: (1) Imperfect opening of the pyloric orifice. (2) Imperfect functional activity of its muscular coat.

The causes which lead to imperfect opening of the pyloric orifice are: (1) Fibrous change in the pylorus, resulting from a pyloritis or inflammation in the neighborhood extending to the pylorus. (2) Spasm of the muscular fibres of the pylorus, depending on changes in the mucous membrane of the stomach, *e.g.*, ulcer or fissure, or changed secretion, as occurs in chronic gastritis—the latter being especially important.

The functional inactivity of the muscularis is of less importance than pyloric stenosis. Complete atony is of rare occurrence, but incomplete muscular power of the stomach wall by delaying gastric digestion can reflexly provoke pyloric spasm.

The operation of either of these two factors is able to cause a stagnation of stomach contents; and so important is the absence of this stagnation to a healthy state of the stomach wall and its secretion that it has been well said: "The cause of all disturbances of the stomach, whether attended by excessive or diminished HCl, is stagnation" (Carle).

Of the two factors essential to the production of stagnation, the pyloric stenosis is probably the more important. Doyen says, in this connection: "The pylorus is the enemy—its excessive irritability is the cause of the most varied gastric disturbances and the most persistent of the anatomical lesions that accompany it."

Assuming, then, for the present that, on account either of a stenosis of the pylorus or of an insufficient action of the muscular coat, there is stagnation of chyme in the pumping-portion of the stomach, need we go any further to explain the pathogenesis of gastric ulcer?

Let us look for a moment to other hollow viscera where there is stagnation of the contents of the canal—the result, for instance, of a stricture. Do we not find in almost all cases of long-standing stricture an ulceration of the mucous membrane above the site of the stricture? In stricture of the rectum is there not ulceration above the site of stricture? In strictures of the œsophagus is there not ulceration of the œsophagus above the stricture? In strictures of the urethra is there not ulceration behind the stricture? Furthermore, such ulceration is similar in many respects to gastric ulceration: it is circumscribed, does not extend marginally as a malignant ulcer, but rather tends to extend into the depths of the viscus. Again, like gastric ulcers, they have sharply cut edges and are in the immediate vicinity of the strictured portion, just as gastric ulceration is in the immediate vicinity of the stenosed pylorus.

The presence or absence of hyperchlorhydria is entirely independent of the production of gastric ulceration. The gastric wall is as well protected from its own digestion by the gastric juice as the blood is prevented from clotting in its own blood-vessels.

I assert, therefore, that the pathogenesis of primary gastric ulcer depends, as ulceration in other hollow viscera, entirely upon the mechanical cause of stagnation; that when an impediment is offered to the outflow of gastric contents, be such impediment a stenosis of the outlet or a deficient propulsive power of the organ itself, then only will ulceration result; that the presence of the gastric juice has no material influence upon the production of gastric ulcer; that auto-digestion of the gastric wall is not necessary to produce a gastric ulcer, and if it were essential it would be as impossible as it is for blood to clot in the healthy living blood-vessels.

We must, then, only find a cause for stagnation of stomach contents in order to explain the pathogenesis of this condition. As I said before, such stagnation is due either to pyloric stenosis or to muscular insufficiency. It has been proven that the condition of the gastric juice in chronic gastritis is such that it cannot carry out its functions either properly or in the required time. Such disturbance and delay in gastric digestion are one of the most frequent causes of evoking pyloric spasm, and this results in stagnation of chyme in the stomach, with consequent dangers of ulceration from purely mechanical causes. Changes in the gastric juice, whatever their nature, if they interfere with the proper functions of the juice, can provoke pyloric spasm and so give rise to ulceration of the stomach wall. In impoverished conditions of the system, such as occur in anæmia, tuberculosis, etc., when the gastric juice is not able to carry out its proper functions, we can readily see how ulceration results; and when we consider in addition the poor muscular condition we have another factor to aid in causing stagnation of chyme in the stomach.

Fissures, when they exist in the gastric mucosa, are of themselves able to evoke pyloric spasm, and so give rise to ulceration of the stomach wall. Furthermore, an ulcer once formed increases the pyloric spasm, and so aggravates the local condition.

We must admit from these premises that gastric ulceration is simply dependent upon purely mechanical laws, just as ulcerations behind strictures in other hollow viscera depend on stagnation behind the stricture; that the presence of the HCl is entirely unnecessary in explaining its pathogenesis.

Let us now look at the clinical picture of this dis-

ease, and see whether its symptomatology harmonizes with this condition. We know very well that many cases of gastric ulcer run their course and never give rise to any clinical symptoms; the patient is never aware of the presence of an ulceration of the stomach, and were it not for the scars which are left behind and which are found on the post-mortem table, their existence during the life of the patient would never have been known. We must infer, therefore, that the ulceration *per se* is not the cause of the clinical manifestations associated with ulcer of the stomach; for why should a certain train of symptoms follow one case of gastric ulcer and not another? The symptoms must evidently be dependent upon another factor, and that factor is stagnation, which was pointed out before as being the cause of most gastric disturbances. In the majority of cases this stagnation is the result of pyloric stenosis, which in turn is most frequently consequent upon some hindrance or disturbance in gastric digestion—a frequent result of chronic gastritis, with the changes it produces in the gastric juice.

What are the symptoms associated with ulceration of the stomach?

(*a*) Pain. This depends to some extent upon the presence of the ulcer, but is increased by pyloric spasm and when there is also present hyperchlorhydria.

(*b*) Hyperchlorhydria, *i.e.*, an excessive amount of HCl in the gastric juice. This is not an invariable symptom, as pointed out before, but is present in about one-half of the cases. Out of forty-four recent cases reported by Carle in Langenbeck's *Archiv*, hyperchlorhydria was present in twenty cases; in nine, normal amount of HCl; in eight, hypochlorhydria; in five, anachlorhydria.

It can be explained as follows: The constant irritation of undigested fermenting food in the stomach provokes an excessive secretion of the gastric juice, and so gives rise to hyperchlorhydria. When there is an atrophy of the peptic and pyloric glands, as is often found in chronic gastritis, we would expect hypochlorhydria or anachlorhydria. It has been suggested that the hyperchlorhydria is the first result of stagnation, and that the excessive HCl causes digestion of the gastric mucosa and so produces ulceration. But this would leave unexplained the fifty per cent. of cases in which there is no hyperchlorhydria, but even hypochlorhydria or anachlorhydria; whereas, if we consider the ulceration as due simply to the presence of stagnation of food behind a stenosed orifice, and the hyperchlorhydria or hypochlorhydria or anachlorhydria as merely an associated phenomenon and the result of the irritation of the glands of the stomach mucosa, we explain all cases on a rational basis. Hyperchlorhydria, then, when it exists, is entirely independent of gastric ulcer, but follows stagnation of food in the stomach.

(*c*) Vomiting depends partly on the stagnation of the food, for by this means the stomach attempts to empty itself. When due to this cause alone the pyloric stenosis must be of a rather considerable degree. It also depends to some extent on the hyperchlorhydria, the excessive HCl irritating the gastric nerves and so producing vomiting reflexly.

(*d*) Hemorrhage. This depends on the ulcer, and occurs when a blood-vessel has been eroded by the ulceration.

(*e*) The symptoms of dyspepsia are dependent entirely on the chronic gastritis, which is usually associated with the ulcer.

Of this train of symptoms, then, that of pain and hemorrhage alone can be ascribed to the ulcer—the former only to a limited extent, the latter entirely. Of the other, the chronic gastritis is usually the forerunner of the entire story. The hyperchlorhydria when it exists is entirely independent of the ulcer, but, like the vomiting, is due chiefly to the stagnation of food in the stomach. If the stagnation is slight in degree, the ulcer is apt to be small and the symptoms are but little marked—the severity of the symptoms being entirely dependent on the extent of the pyloric stenosis or muscular atony and the consequent stagnation which they produce.

Having thus set forth the grounds upon which I consider the pathogenesis of gastric ulcer to be the result of pyloric stenosis, or, in rare cases, muscular atony, and the consequent stagnation which they produce, I would like to say a few words as regards the therapeusis of gastric ulceration, considered from this standpoint of its etiology.

Until quite recently gastric ulcer was claimed to be entirely in the domain of the internal physician, but the pendulum is commencing to swing in the opposite direction and the surgeon's aid is commencing to be more and more invoked in the treatment of those cases which have not yielded to the healing powers of medicines and diet; and his calling has not been in vain, as recent statistics well show.

In laying down a rational therapeusis of this affection, let us see what are the conditions that must be satisfied and how we deal with them in other parts. When we wish to heal an ulceration behind a stricture or stenosis in any hollow viscus, we do away with the cause of the ulceration, *i.e.*, divide the stricture or remove the stenosed part. We should be but rarely successful in our endeavors to heal the ulcer if the cause for the ulceration were left behind. And yet we have treated gastric ulcers in just that way—we have considered the ulceration as an entity in itself and have treated it in that light, whereas, from the foregoing considerations, we see it is not a pathological entity, but only one result of gastric stagnation. What, then, must we consider to be the rational therapeusis of gastric ulcer? Firstly, we must remove the pyloric stenosis; secondly, increase the functional activity of the muscular coat. If these two factors are met and satisfied, the stagnation in the stomach will be removed, and the ulcer, the result of stagnation, will heal spontaneously. How, then, are we to meet these two factors? (*a*) By medical means; (*b*) by surgical means.

Medical Therapeutics.—We have said that chronic gastritis is a very frequent cause of pyloric spasm. Our efforts, then, must be directed to the alleviation of the chronic gastritis, if we would do away with the spastic condition of the pylorus. If we interview our patients with gastric ulceration, we will find that the majority of them give an initial history of quite severe pyloric pain, gastric distress, and noises in the stomach for several hours after eating—a history pointing to pyloric spasm and commencing gastric stagnation. This is the stage when ulceration can be avoided if the proper prophylactic measures are taken. These measures are: (1) Regulation of diet; (2) aiding digestion by ferments; (3) increasing the muscular tone of the stomach wall.

When an ulceration exists, our therapeutics must be directed in the same channel, *i.e.*, attempting to remove the stagnation by doing away with the pyloric spasm. The chief method we rely on is the regulation of the patients' diet. I do not consider it necessary to exclude all solid food from the regimen of these patients, but only such food should be allowed as can be easily passed through the spastic pyloric orifice. This includes (1) general fluids; (2) soft, mushy articles of diet, such as zwieback, toast, and raw eggs.

All food which tends to leave large pieces in the stomach, to be propelled onward into the duodenum, must be carefully withheld. All food which does not mix well with the gastric juice must also be avoided, and all irritating articles of diet which increase the gastritis must be forbidden. The food must never be

taken in large quantities, but in small amounts and frequently.

Lavage of the stomach is often of value in those cases in which the symptoms of chronic gastritis are very marked. Hemorrhage, or indications of deep-seated ulceration, *e.g.*, local peritonitis, would of course contraindicate such procedure. Lavage not only serves to benefit the gastritis, but also removes the stagnant material from the stomach. In performing lavage we should never distend the stomach to its utmost, but, having found out how much the organ will hold, pour a little less than this amount into it at each filling.

As regards medication, I consider only such medication to be warranted as will directly benefit the condition of the stomach. The use of bismuth or other insoluble salts, on the theory that they will form a coating to the ulcer beneath which healing will occur, is to me entirely without basis, for healing will occur without these protecting coats of insoluble salts if the head and front of the offending are removed. Similarly the use of nitrate of silver, with the hope of forming a coating of albuminate of silver for the ulcer, is without *rationale*. When, however, the plyoric spasm is intensified by the presence of the ulcer, as indicated by intense pyloric pain, the use of the insoluble salts by protecting the surface of the ulcer will do away with the reflex spasm, and so serve a useful purpose.

Besides this, medication should be directed to aiding gastric digestion with the artificial ferments and improving the tone of the gastric muscle. The symptomatic treatment should be carried out as the symptoms arise.

Leube has recently advised the use of hot fomentations to the gastric region, continued for ten or fourteen days' time. I have had no experience with such extended use of local heat, but should surmise it to be of value in reflexly lessening pyloric spasm.

Rest in bed, if the general tone of the patient is a poor one, *e.g.*, in overworked anæmic individuals, restores that tone to the patient, improves the condition of the gastric juice, and so aids digestion and propulsion of food contents into the duodenum. Otherwise a fair amount of exercise should be demanded of these patients.

Surgical Treatment.—I have already said that the treatment of gastric ulceration is being more and more looked at from a surgical standpoint. I do not by any means wish to convey the idea that all cases of gastric ulceration must be subjected to the knife. Leube has given the statistics of four hundred and twenty-four cases of gastric ulcer, seventy-four per cent. of which were healed by medical means. It would obviously have been wrong to have subjected these cases to operation; but in cases in which medical measures have been tried and found wanting the surgeon's aid should be enlisted. Mikulicz says in this connection that "one needs only to see such a patient before operation and six months after operation to be convinced of the value of surgical interference."

The special indications calling for surgical interference have been so well expressed by Leube, in a recent article, that I will quote them in full. He considers them as relative and absolute.

"(*a*) Hemorrhage. (1) Absolutely indicated by continuous oozing of blood, especially if there is an associated gastrectasia. (2) Relatively indicated by profuse hemorrhage, but operation is contraindicated in a single profuse hemorrhage, when opium and ice should be used.

"(*b*) Progressive inanition, dependent upon severe pain and continuous vomiting, constitutes a relative indication for gastro-enterostomy.

"(*c*) Perigastritis, adhesions between the stomach and neighboring parts, subphrenic and other peritoneal abscesses, constitute indications for surgical aid; absolutely, when an accompanying abscess exists and when the walls of the ulcer are so much thickened as to be felt through the abdominal wall.

"(*d*) Sudden perforation into the free abdominal cavity absolutely indicates surgical interference, and that as early as possible after the initial shock; but operation is not indicated in cases of gradual perforation, accompanied as they are with adhesions to neighboring viscera. Here opium and rest are to be preferred."

The indications for surgical interference having thus been laid down, the question next arises, What should such interference be? One of two procedures is open to the surgeon: (*a*) pyloroplasty (Mikulicz-Heinecke); (*b*) gastro-enterostomy—that is, a procedure which will do away with stagnation of the stomach contents. Of these two procedures, the pyloroplasty whenever it is possible should be done; but it may happen, on account of adhesions to the neighboring parts, that the pylorus is not accessible and cannot be drawn out of the abdominal cavity. In these cases a gastro-enterostomy is to be preferred. The recent statistics of Mikulicz on pyloroplasty and gastro-enterostomy for ulcer are:

1891–1897.	Cases.	Healed.	Died.	Mortality Per Cent.
Pyloroplasty and gastroplasty..	76	66	10	13.2
Gastro-enterostomy	68	57	11	16.2

The ulcer itself, unless it has given rise to hemorrhage or abscess, needs no treatment; the removal of the cause will be followed by its spontaneous healing, for it has been proven by Mikulicz that when the pyloric stenosis accompanied by ulcer has been relieved, thus securing a complete and rapid emptying of stomach contents into the duodenum, the ulcer without any other treatment healed spontaneously.

In concluding this paper, I would like to sum up the principal points I have mentioned:

1st. That gastric ulcer is not a unique condition, but bears a strong resemblance to ulcers in other parts which have a similar pathogenesis.

2d. That auto-digestion of the living gastric walls by gastric juice is as impossible as for the blood to clot in the healthy living blood-vessels.

3d. That gastric ulcer is due to stagnation in the pumping-part of the stomach behind a stenosed orifice —be such stenosis a spasm or an organic stricture of the plyorus.

4th. That hyperacidity and the other clinical manifestations are dependent on the stagnation.

5th. That the treatment, whether medical or surgical, must be directed to the cause of the ulcer, *i.e.*, in removing the pyloric stenosis.

Cause of Death after Extensive Burns. — The cause of death after burns is a toxic ptomain, and is not due to the toxins which may be produced in the burns by bacteria, or to anatomic changes which the blood corpuscles or the organs of the burned area may have undergone.—Agello *and* Parascandolo.

CEREBRAL HEMIPLEGIA FOLLOWING DIPHTHERIA, WITH REPORT OF A CASE.[1]

JOHN WINTERS BRANNAN, M.D.,
NEW YORK.

Paralysis in some form is a very frequent sequel of diphtheria. According to Gowers, one-fourth of those who do not die from the primary disease suffer subsequently from paralysis. It is as frequent after mild as after severe attacks. The most common form is paralysis of the palatal muscles, causing regurgitation of food and nasal voice. Paralysis of the ocular muscles, especially those of accommodation, is not infrequent. The lesion, though not always the same, is generally considered to be a peripheral neuritis. The extremities are sometimes affected, the neuritis then being multiple. Recovery is the rule in all of these forms. The case I have to relate is of another kind and of a much more serious character.

The case is that of a young woman of nineteen, who was sent to the Reception Hospital in Sixteenth Street, on June 3, 1896. She had been ill for several days, under the care of Dr. Packard. She appeared to be fairly strong, but rather anæmic and of a nervous, excitable temperament. During her first two days in the hospital she had several hysterical attacks. The diphtheria was of a severe type, affecting the nasopharynx, with profuse nasal discharge. There was albumin in the urine, and it persisted up to the date of her discharge from the hospital. There were no other symptoms of nephritis, such as suppression, casts, or œdema. The heart was normal throughout, and the pulse was of good quality.

As the patient had been ill for several days previous to her admission to the hospital, Dr. Packard thought it as well not to give antitoxin. The treatment consisted of frequent irrigation of the nose and throat, according to the usual method employed in the Willard Parker Hospital, and free stimulation with whiskey and strychnine. The throat was clear of membrane in a week and there were no unfavorable symptoms, with the exception of the albuminuria, which was slight. The mother of the patient was at the hospital with her, and was most anxious to take her to her home in Meadville, Pa., at the earliest possible moment. The cultures from the throat were free from bacilli on June 18th, fifteen days after her admission, and on that day the patient left with her mother. She had been up and about her room for three or four days, and just before she left it was noticed that her voice had a slight nasal tone. The mother understood that we did not approve of her daughter's leaving so soon, and promised to keep her as quiet as possible after reaching home and to place her under the care of their family physician.

About two weeks later I heard indirectly that the patient had been suddenly seized with paralysis of the leg and arm on one side, accompanied with loss of speech. Bearing in mind the hysterical character of the girl, I was not inclined to believe that the paralysis was genuine. I accordingly wrote to the mother that that form of paralysis did not occur after diphtheria, and that it would probably soon pass away. A few days later, however, I received a letter from the attending physician, Dr. W. D. Hamaker, which promptly convinced me of my error. The letter is so well expressed that I give it in full:

"When Miss ——— arrived home she seemed to be doing very well, but a few days later she developed symptoms of postdiphtheritic paralysis, shown only in the throat muscles—some difficulty in swallowing and a nasal tone to the voice. A few days later I was sent for early in the morning, and found her right arm completely paralyzed. This passed away entirely in about two hours. On the two following days she was very well, and could not be induced to observe care—she felt so well. That evening she was seized suddenly, while preparing to retire, with paralysis of the right arm and right side of the face, with loss of speech. By morning the paralysis was complete on the right side. Up to the present time (July 4, 1896) she has had no return of speech, the arm is helpless, but she is able to move the foot and leg a little. The tongue protrudes almost straight; swallows well; some appetite. General condition fair. Some albumin in urine. Anæsthesia of arm and leg almost complete at first; at present not marked. Our diagnosis has been hemorrhage in left side of brain."

It was evident that there was a vascular lesion in the left hemisphere, but I was inclined to think it rather of the nature of a thrombosis, considering the youth of the patient and the transient character of the first attack of paralysis affecting the arm.

On July 14, 1896, I received a second letter from Dr. Hamaker, stating that the patient had improved somewhat; she was able to speak one or two words, and had regained some power over the leg. The right side of the face showed some improvement: no power had returned to the hand or arm. Albumin had disappeared from the urine. He thought the case was one of hemorrhage, because there had been no history of rheumatism and there were present no symptoms of any heart disease. The valvular sounds were normal.

A letter received yesterday from Dr. Hamaker informed me that the patient was now able to walk with a very slight limp, but that she had little use of her hand. Mentally she was as bright as ever, but there was not much improvement in her speech. On two occasions she had had severe convulsions—once after some unusual fatigue, the second time on rising in the morning.

As I have already intimated, postdiphtheritic paralysis of cerebral origin is extremely rare. Most writers on nervous diseases and on diseases of children fail to mention it at all. Gowers gives it four lines, although he devotes sixteen pages to the usual forms of paralysis following diphtheria. There are thirty-five cases in all recorded in medical literature. The case I have just reported is the only known instance among the thousands of patients treated at the Willard Parker Hospital during the past few years. As the paralysis does not occur, as a rule, until convalescence is established, it is quite possible that it may have occurred in some of the patients after they had left the hospital.

The cause of the paralysis is not always easy to determine. In the thirty-five reported cases the lesion was thought to be hemorrhage in seven cases and embolism in fourteen; in the other fourteen the diagnosis was uncertain. Six cases have come to autopsy: in one of these a hemorrhage was found in the internal portion of the lenticular nucleus, with destruction of the neighboring part of the internal capsule. In the other five cases there was embolism of the Sylvian artery. Whether the vascular lesion be hemorrhage, thrombosis, or embolism, it is probably situated in the internal capsule in the great majority of cases. Postdiphtheritic cerebral hemiplegia is most common in children from eight to fifteen years of age. The prognosis is grave, as in similar lesions in adults. In the total thirty-six cases, there was complete recovery in four, death in seven; in all the others there was permanent paralysis of greater or less extent.

Tetanus.—Of twenty-four patients treated with antitoxin, twelve recovered and twelve died. The less violent the symptoms the better the results.—Webber, *Lancet*, 1897.

THE STUDY OF EPILEPSY.

By EDGAR J. SPRATLING, B.Sc., M.D.,

FIRST ASSISTANT PHYSICIAN, MASSACHUSETTS HOSPITAL FOR EPILEPTICS, PALMER, MASS.

This should be undertaken with the full appreciation of the fact that the seizure or fit is only one of a group of symptoms; it is the pathognomonic sign, and should be studied as such and not as the disease itself. Its appearance at this or that time would not by any thinking man be ascribed to accident; neither would he think of it as being *ipso facto*, but rather as the culminating phenomenon of a series of abnormal, or at any rate untoward conditions, which may not individually be pathologic, but when taken together reach the one inevitable climax.

A function may be simply perverted by extraneous circumstances, without its parent organism being actually diseased; and so a condition of tissue predisposing to a certain disease may be congenital, yet the disease never develop. One may have intestinal glands peculiarly fitted for the lodgement of the typhoid bacillus and yet never become infected. And so we might go through a whole catalogue of negative conditions, and what applies to any disease applies just as forcefully to epilepsy. There must be present the necessary histological formation of the cells, together with an inciting cause, to make it a possibilitity in any given subject. This histological formation must be developmental, most likely prenatal, or degenerative, in the elements of at least one set of brain cells, and some physiological function be perverted to act as the immediate incentive; probably in every case more than one such factor is present.

Among such derangements of physiological functions causing epilepsy, malassimilation with its parent dyspepsia holds without dispute in my mind first place. This is particularly true of the cases prone to pass into the so-called "epileptic state," which is largely a resultant maniacal delirium with exhaustion, complicated by toxic infection, giving high temperature; if not promptly relieved, generally resulting in death. The writer has found by experiment in many cases that as soon as the intestinal tract was made absolutely clean the epileptic state would have disappeared, leaving a sound sleep and a quiet awakening. The matter ejected by the cleansing of the alimentary tract would be found highly acid, while the normal secretions would be very scarce. Badly digested and imperfectly assimilated food mean a systemic poison, just as truly as any ptomain received into the body would be poison.

Probably the inciting cause next in importance is an abnormal arrangement or disarrangement of some portion of the body; certainly each case of the so-denominated Jacksonian variety has such origin. It may be the remains of an old neuritis, the scar of a gastric ulcer, an obstetric injury, or any other injury, or it may start from an ear disease, an eye strain, or a tumor, and a partial convulsion caused thus may become general and obscure the real type to which it should be referred. We see by that that the history of every case must be inquired into minutely; a great many more cases than are generally supposed begin in this way, and by the time they are studied by the neurologists the real type is lost and often even the aura itself has ceased to recur, and the convulsive habit has been so firmly fixed that the real origin may have ceased to exist without being missed. In this group syphilis plays its greatest rôle; and here also belong most of the senile and postparaplegic cases.

Let us put mental activity third in our list of causes, and we shall be surprised to find it covering such a multitude of factors, only a few examples of which need be mentioned. Remember how many cases begin in childhood at fright, and in youth from ill-advised or excessive work, disappointment in love or honors. This type is particularly liable to be confused with hysteria, nearly always so in the female; and the immediate cause is the suspension of higher control or the depression of vitality.

And giving the same causative effect as this will be our next group—physical overwork, insufficient food or lack of variety, continued illnesses, and like conditions.

It does not seem necessary to make other divisions, as every possible case can find its home in one of the four given above. Probably in every instance will be found more than one factor in the immediate etiology, the necessary strength of these factors to produce a convulsion being in inverse proportion to the peculiar developmental fitness of the brain cells. Because a drug may produce a convulsion in any individual is no argument that every one could become an epileptic, as the conditions are entirely different in kind.

Now by these statements of causes we are led to the question, "How should epilepsy be studied?" and the answer could only be, study each case as to its causes. And now let us comment briefly on a few indicative signs and symptoms.

Heredity of course plays its part by a prearrangement of the tissues. It is true that a fœtus may be epileptic, and to be so its cell development must be strongly inclined that way, together with an immediate aid, such as bad nutrition, an uncomfortable position, or an injury. On the other hand, the mother may be affected independently of the fœtus; but the child of an epileptic would stand less chance of passing through life untouched than would the offspring of a normal parent. That is likewise true of the child of an alcoholic or of a person in active tuberculosis or cancer.

After these prenatal and other histological factors are duly considered, we should observe closely the kind of aura or onset when it is sufficiently removed from the spasm to admit its being noted separately, and even in cases usually said to have no aura by close observation we shall find that there is generally some special sensation or act that precedes unconsciousness and the pronounced spasm. If this be referred to the gastric, cardiac, or encephalic regions, or vaguely to the skin, we most likely have to deal with poor nutrition and its accompanying disorders. Feelings of heat, cold, or muscular twitchings, visual and auditory disturbances, and subjective vertigo are peculiarly apt to go with bad nutrition.

While pain, itching, heat, or cold, referred habitually to some definite region, will most likely be indicative of an old trauma, remains of an old neuritis or perineuritis, or something allied, always note carefully for syphilis here.

Indications for causes within the third group will at once be seen to be the most indefinite and the hardest to utilize in making a diagnosis; but feelings of sudden fright, of vague, causeless fear, of depression or elation, would lead us in that direction. We ought here to have also the aid of an accurate history.

Flashes of light and objective vertigo would point to some cause within the fourth group; and here we generally have irritated stomachs, dilated, irregular, or irritable hearts.

The examination of every epileptic should include each point mentioned above, and special attention should be given to following out any indicative sign or symptom. By studying the seizure itself closely, we shall often find in it some peculiarity which will lead us to the real nidus of the spasm.

The pathology of epilepsy *per se* is as yet hidden from us; it is only when insanity or some other complication has set in that we find pathological con-

ditions gross enough for our comprehension by the means at present at our disposal. But that there is an organic difference in the brain cells cannot be seriously doubted. The seizures produce no change beyond exhaustion, and direct medication to prevent them must in the long run be futile. Only by modifying the conditions can we hope for success in the highest sense, but by the removal of the immediate causes we may prevent the seizures and cover most of the other symptoms; to outward appearance recovery has been achieved, and still the future is filled with pitfalls into which we may at any time blindly step, the seizures returning with renewed force.

As to the treatment, we defer consideration of that to some future season. In the mean time let us feel that the work of the neurologist in our time is so to improve the histological structure of the cells themselves as to make the epileptic condition an impossibility.

SUBJECTIVE THERAPEUTICS.

By W. P. HARTFORD, M.D.,

CASSVILLE, WIS.

Our duty, pleasure, and profit as regular physicians lie in curing our patients, and we should use any and every means at our command to attain that result. The brightest lights of the medical profession are at work discovering new remedies for disease, new surgical operations, and new uses for old remedies. But, in spite of all, there is still a class of patients who drift away to the quack, the mind cure, the Christian science cure, the Keely cure, or the hypnotist, and return cured. We say "Bosh!" "Humbug!" and "Hysterics!" But that does not convince the patient or deter him from sending a few of his acquaintances to the same cure. It would certainly be more profitable to us if we should investigate those cures and discover the underlying principle of them, turning it to our own use, instead of leaving it in the hands of the charlatans.

A careful analysis of all the methods that have been in vogue show the utmost divergence in everything except two points—faith on the part of the patient and suggestion on the part of the healer. Mind curers boast that faith is unnecessary. A close analysis, however, shows this boast to be in vain, for this mere assertion that faith is not needed would be the best method in many cases of causing the patient to think there might be something in it. Then a potent factor in awakening faith is seen in the practitioner who dispenses with all medicines and manipulations, and gravely assures the patient that he is not sick, never was sick, and never will be sick. Then there is a silence of fifteen or twenty minutes, during which time the patient watches the confident expression of the healer's countenance and wonders if there can be anything in this. "There must be. Lots of people have taken this treatment and are well. I believe it will help me." Then the words of the healer on departing are encouraging, and, the entire treatment being pleasant rather than otherwise, he longs for the next treatment. After a while he believes that he is better, and the stronger that belief becomes the better he feels, until finally he is well and goes forth a very active advertisement for the mind curer.

The Christian scientist proceeds in a slightly different manner. The association was organized by Mrs. Mary Baker Glover Eddy, who claims to be the great, only, and original metaphysical healer. She was cured of some mysterious malady in 1862 by a mesmerist, Mr. P. P. Quimby. Later, she says, she met with a terrible accident and received injuries which physicians pronounced fatal, but God in answer to her prayers healed her in a few hours. She organized the Christian Scientist Association in 1876, and a mind-healing church called the Church of Christ in 1879. She has written a number of pamphlets. The fees in the original Christian science college are $300 for the first twelve lessons, $200 for the next six lessons. Six lectures teach metaphysical obstetrics at the nominal price of $100, and to be a full-fledged Christian scientist the six lectures in theology and the Scriptures must be crammed into the already overflowing brain at an additional cost of $200. Several of her students have started colleges of their own, and have cut prices to such an extent that some of them agree to tell all they know for $25 and to throw in a diploma.

Mrs. Eddy has had a great deal of trouble with these impostors, but in the fundamental principles they agree with her, differing only in minor points. Her theory is: Nothing is real except the divine mind; matter is not real, therefore does not exist; it is impossible for disease to exist where there is nothing; therefore there is no disease. And, silly as this whole system is, she and her followers have cured hundreds of cases by the mere suggestion that there could be no disease present. An examination of the works of Mrs. Eddy, Evans, Grimke, Stuart, Arens, Tayler, Baldwin, Hazzard, Nickols, and Marsten will convince the most sceptical that their cures are accomplished entirely by suggestion.

Other cures owe their success to the same cause, but the suggestion may be made more or less striking, according to the mental peculiarities of the patient and by the most diverse methods. All, however, have the same end—that is, to suggest to the patient that the disease is about to be cured. Mesmer healed by stroking the affected parts with magnets, suggesting to the patient that the magnetism would so permeate their bodies that it would cure them. He practised this for ten years, when he learned that Gasner obtained the same results without the use of magnets. So Mesmer discarded magnets and claimed that the magnetism emanated from his own body in quantities sufficient to cure any disease. To give the utmost force to his suggestions, he had his consulting-apartment dimly lighted and hung with mirrors. Soft music broke the silence. The patients sat around a simmering vat of supposed magnetism. A wire carried the subtle fluid from the vat to each patient. Then, when they were sufficiently impressed, Mesmer, dressed as a magician, would enter and glide among them, making passes and suggesting that their diseases were passing away.

Joseph Smith, the founder of the Mormon church, cured his followers by prayer and the laying on of hands. All the priests and missionaries of that faith practise the same thing yet, as I know to my sorrow, they having captured several delightful old chronics that I thought I had for life.

The miraculous spring at Lourdes cures many each year. Prince Hohenlohe cured thousands. Many of his cases are as well authenticated as any facts in history. Gasner also cured by suggestion. Father Mathew's power did not die with him, for people are still cured by merely touching his tomb. In all parts of Europe are churches in which may be seen stacks of crutches, splints, and canes, thrown away by the happy souls who have been cured by the sight or touch of sacred relics. I know a man who makes a very comfortable income by magnetizing pieces of tissue paper. His patients tie them around the great toe, and they cure the rheumatism in that half of the body. Knock Chapel, in Ireland, has many cures to its credit. W. E. Boardman, in his establishment called the Nursery of Faith, in London, cured paralysis, rheumatism, consumption, and cancer by prayer and anointing the body with oil.

Hypnotism holds a place as a purely suggestive therapeutic agent, ridiculed by its enemies and lauded as

all-powerful by its friends, both of whom are laboring under delusions in regard to its efficacy.

Among the semimedical, semisuggestive cures may be mentioned some sanatoriums, quacks, patent medicines, and, last but not least, that ubiquitous individual who has a wonderful remedy that cured somebody that had just exactly the same symptoms. I do not wish to deny the fact that almost invariably the cures by suggestion have been exaggerated—the relapses and failures have not been reported. Many reported cures were not cures at all: for instance, the case of a boy with a broken arm, cured in twenty-four hours by prayer, on being investigated proved to have been a greenstick fracture that had been diagnosed and straightened by a physician. A man who had been walking on crutches six months threw away his crutches and walked away cured instantly by Schlatter. He had been under the care of a noted surgeon, who treated him for a fracture of the femur. The truth was, his leg had been perfectly well for months, but he imagined he could not bear his weight on it, until Schlatter suggested that he was well.

These cases were advertised as miraculous cures. In fact, people seem prone to magnify any cure that partakes of the suggestive. The regular physician or surgeon seldom receives more than a fraction of the praise bestowed on the charlatan. His cures are taken as a matter of course, and he can remove a tumor or cure a fever without eliciting any comment, when if the same results had followed a prayer or the laying on of hands or an hypnotic *seance*, it would have been deemed a miracle. Patients would flock to the healer. All who had implicit faith would be more or less relieved by the suggestions received, and go forth spreading the joyful tidings and recommending that particular method. Those who received no benefit would say nothing, or would deny they had been silly enough even to try such a humbug. The healer, if moderately sharp, would in a week treat more patients than the average physician would in a year, and the aggravating part of it is that the confirmed old hysterical grunter, who has made herself and all her neighbors believe she was at death's door with a mysterious malady that the doctors were all powerless to diagnose or relieve, is cured. We say we are glad to get rid of the hysterical old nightmare, but in reality we should be far better pleased had we cured her ourselves.

There is a class of cases that these humbugs cure by suggestions. It is a legitimate remedy, and has its limitations, which can be as well defined as those of any other remedy. I can assert without fear of successful contradiction that the involuntary acts of the body can be influenced by the mind—that the mind has an effect on the action of all the organs supplied by the sympathetic nerves. The emotions, joy, fear, etc., can accelerate or retard the action of the heart, lungs, stomach, etc. The emotion fear has caused instant death. Sorrow has killed many. Joy has a beneficial effect. All the emotions play an important part in controlling bodily functions. Hudson claims that man has two mental organizations—an objective mind that reasons, and a subjective mind that is controlled entirely by suggestion. It is the seat of the emotions, cannot reason inductively, and has complete control of all the purely vegetative functions; it believes every suggestion not positively contradicted by the objective mind. Allowing this theory to be true, all cases of suggestive healing are easily explained. The subjective mind receives the suggestion, and, not being able to reason inductively, believes it and at once proceeds to cure the disease.

Faith is really nothing more than auto-suggestion. Faith and suggestion play a very important part in the practice of the regular practitioner. The patient thinks the doctor can help him; he believes the treatment will be beneficial; and the stronger his faith is, the more good the treatment will do him. Many of our most progressive physicians are advocating the use of fewer drugs and more suggestion. All of us have seen cures that the treatment would not account for, but that the theory of the subjective mind and suggestion will explain. In fact, we can by that hypothesis analyze the mind of any one, foretell what he will be liable to do under any combination of circumstances, whether we can better control him by reason or suggestion, whether he needs drugs or advice, or both.

A person with the objective mind in preponderance will be cool and calculating, will believe nothing he cannot reason out. Explain his disease to him, explain the action of the drugs, give him a complete diagnosis and prognosis, and prove both to him in the strongest manner possible. His reason dominates his soul—or, in other words, his objective mind controls his subjective mind—and it will receive nothing but auto-suggestions.

At the other extreme is the person with the subjective mind in control. This person will be emotional, poetical, musical, and religious; will believe anything reasonable and almost everything unreasonable. Say little about the disease, but a great deal of the wonderful efficacy of the treatment. Take great interest in the case, ask a great many questions, look as wise as an owl and as sympathetic as you can, but by all means impress upon her the belief that you understand her case thoroughly. There are a few to whom you may explain the action of the mind and let them help themselves by auto-suggestion. Many of us fail to comprehend what a powerful ally we have in the subjective minds of our patients, and what an important part suggestion plays in the cure of disease. When our patients come to know that we understand the underlying scientific principles governing these cures and are able to use the same means supplemented by the proper medical treatment, a hard blow will be struck which will cripple the faith healers; and if we, with our powers of diagnosis and mental analysis, our knowledge of drugs, our ability to select the proper cases for suggestion, cannot far surpass any of the army of healers, I am very much mistaken. None of them, so far as I can learn, has the slightest idea of the manner in which their suggestions act on the body. They are unable to diagnose or select their cases. Each has his or her pet method of suggestion, and, hit or miss, hysteria or cholera morbus, old or young, male or female, all have to take the same thing. Of course the failures are many, the real cures few; but they are as successful as we would be were we to confine ourselves to a single drug for all cases; and it is a fact that cannot be refuted that, however different their methods are, they all agree in one thing and one only—that is, suggestion. Lack of space has prevented me from presenting arguments and illustrations to prove the various assertions I have made, but I hope they are so self-evident as to require no such arguments.

But most psychological subjects, if carried far enough, enter the domain of the unprovable, and this one is no exception, although I think the following assertions are as near proved as is the action of any of the remedies we make use of, and if allowed to be true explain many points that have heretofore been deemed undemonstrable. No one who has ever had a dream or participated in a hypnotic *séance* but will admit that we still possess a mental organization when the reasoning faculties are in abeyance. Let us, for lack of better terms, call the reasoning faculties the objective mind, and the mind that is amenable to suggestions the subjective mind. Let us admit that the subjective mind has more or less control of the bodily functions.

The London Society for Psychological Research, in a carefully conducted series of over three thousand experiments, has proved beyond a doubt that it is possible for one person to communicate thoughts and emotions to another by what is termed mental telepathy, and, as this can be done most successfully in the hypnotic state, it stands to reason that the subjective mind receives the message. Allowing these theories to be tenable, we have a clear explanation of the occasional success of "absent treatments." Again, if the subjective mind or soul is a part of the great Supreme Intelligence, a part of Deity, and returned to Him at the death of the body, it is possible that our subjective mind may receive suggestions from that source, and thus disease be cured directly by divine interposition. From our earliest childhood we are taught that our principal duty is to prolong life, that health is a blessing to be sought for by all means. The subjective mind, under this battery of suggestions from all sources, naturally tries to keep the bodily functions up to par, and I think this theory may explain why the tendency of all disease is toward recovery. When reason decides that life is not worth living and conveys this idea to the subjective mind by auto-suggestion, death will often ensue. The homesick soldier or sailor will die of injuries that would be recovered from at home. The death rate of a defeated and discouraged army is always great. The young girl disappointed in love and the bankrupt business man are invariably in poor health. Take two men identically the same physically, give them precisely the same food and hygienic surroundings, let one be happy and contented and the other prostrated with trouble, and it requires no prophet to tell which one will live longest. The theory that the subjective mind controls the bodily functions and is itself controlled entirely by suggestion, explains all these hitherto unexplained problems. It is the true theory, but, like all new ideas, it is destined to run the gantlet of adverse criticism.

It has been suggested to us in every way from our earliest recollections that the soul is a mysterious something that cannot be reasoned about, and it strikes one as something bordering on sacrilege to be told that it can be analyzed, its powers and functions described. Any one will admit he has reasoning faculties, that it is possible for him to become insane or demented and lose the power of reasoning inductively. Nearly every one will admit that he has a soul, and that the idiot that cannot reason has a soul, but when we tell them there are an objective and a subjective mind they call us cranks; but this hypothesis has been proved true. It solves every psychological problem that can be brought up, but, as with all great discoveries, it will be years before it is generally accepted. In the mean time I see no good reason why we should allow the army of irregulars to carry away the best part of our business. If a patient once knows that the miracle cure is no miracle, that we not only understand the miracle but the scientific reason for it, we have saved him, pocketbook and all. We are supposed to temper the wind to the shorn lamb, but we can better afford to do so if we have a hand in the shearing.

Chronic Intestinal Obstruction.—There may be an acute appearance. This late-coming acuteness may be mistaken for an early acuteness, and the fact that the mischief is probably in the large intestine may thus be overlooked.—Jacobson.

Appendicitis.—I will give it as my conclusion that the safest plan of management of all cases of appendicitis, take them as they come, is the immediate removal of the appendix and the drainage of the infected cavities.—Bernays.

WHEN LANCET WAS KING AND CALOMEL PRIME MINISTER.[1]

By James Weir, Jr., M.D.,
Owensboro, Ky.

Mr. Smith returned to Smithville by water from Cincinnati on Saturday, the 3d of May. I saw him on Sunday morning and observed to him, I think, that he looked more fleshy and in better health than I had ever seen him. He informed me that he had been very much exposed, on the ride up, to bad weather, it having rained on him every day for a week, and that he had suffered a good deal of fatigue from a very indifferent riding-horse, but that, nevertheless, he felt pretty well except for a rheumatic affection of one of his knees, which I observed to stiffen his walk some little.

On Monday (the 12th) in passing his store he called me in, and complained of some headache, which he said was an unusual thing with him, and proposed bleeding for it. Knowing his partiality to the lancet in all cases, and not conceiving that the state of his pulse particularly required it, I suggested to him the use of a purgative. This he assented to and took a tablespoonful of Epsom salts. As well as I can recollect, upon inquiring into the state of his knee he informed me that he had the day before applied the essence of mustard freely, and that his knee was better, the swelling having already entirely subsided.

On Tuesday (13th) he sent a message to my house, desiring me in returning to my shop after dinner to call on him. I did so, when he informed me that the salts had operated freely, that his head was easier but still somewhat pained, but that he felt generally more unwell. Upon feeling his pulse there was evidently an increase in its force and frequency; and I then suggested to him the propriety of bleeding, to which he readily assented, and twelve or sixteen ounces of blood was taken. He was directed to make use of a warm bath to his feet and legs, and to drink freely on going to bed of some warm herb tea.

On the next day (Wednesday, the 14th) he told me that he had rested pretty well through the night, that the bath and tea had succeeded in producing a free perspiration, and that he thought he had no fever through the night. His pulse, however, when I saw him this day was feverish and I prescribed a dose of calomel at night; he took twenty grains.

Thursday (the 15th) I visited him and was informed that the calomel had operated freely, having produced considerable nausea at the stomach. In the evening there was considerable increase of fever and he was again bled, to the extent, I suppose, of nearly a pint.

Friday (16th), some feverish state still remaining, he was directed to use freely the cream of tartar, to drink through the day, to observe light diet, etc.

Saturday (the 17th) he was up (having, indeed, never been confined to his bed) and at his store nearly all day, and thought himself much better. He called on me in the shop in the evening, and, upon feeling his pulse, I found them a good deal increased in frequency from his exercise, beating near 100 in the minute. His tongue was also somewhat furred. I thought it best he should take more calomel, and fifteen grains were presented, to be taken at bedtime.

Sunday (18th) he professed to feel better, but the calomel not having operated to his satisfaction, he took in the morning a dose of Epsom salts, by which his bowels were freely opened. He walked about his house and lot the greater part of the day, and eat some, perhaps a saucer full, of strawberries and drank a little buttermilk.

[1] This "report of a case and its treatment" was taken *verbatim et literatim* (names only being substituted) from the notes of a celebrated physician who died some ninety years ago.

Monday (19th) I saw him quite early in the morning, when, for the first time, he showed me a small inflamed spot on his foot, which he said had been considerably painful through the night; that he had been feverish and had not slept well. He complained also of some uneasiness in the joint of the larger toe of the affected foot. His pulse when I visited him in the morning was beating somewhat upward of 90 in the minute, and was full and strong. I bled him again to the extent of about twelve ounces, when I discovered a manifest reduction in the frequency of the pulse, having fallen to about 64 in the minute. Before I left the house, however, I discovered a disposition in it to rise again, and with the wish of keeping down the fever I prescribed the ordinary cooling antimonial powder, one of which he took at 8 A.M., and another at 11 A.M. About 1 P.M. I was sent for and found him laboring under considerable pain of the bowels, and was told it had been the case for an hour, during which time he had had three or four brisk operations on them. I immediately gave him thirty drops of laudanum with ten of peppermint essence, and repeated nearly the like quantity in half an hour, shortly after which, by the aid of hot applications locally, he became easy. I left him about four o'clock in the afternoon, as I, having occasion to go into the country, did not see him again until nine o'clock, and was then told that the pain had returned shortly after I went away, which was again relieved by the means before used. While I remained with him he continued easy and I left him at ten, with the prospects of his spending a good night from the sleepiness which the laudanum had already produced. Little did I anticipate the dreadful nights and still more dreadful days which awaited him! I was to see him in a short time, and found him in agony so great as to force from him the exclamation, "Doctor, I shall die!" The pain in his bowels, about the navel, had returned with increasing violence, and extended occasionally to the privates. There was, however, at the time no tumefaction whatever. I requested the aid of Dr. Hunter in consultation, who came over immediately, and we determined upon evacuating his bowels freely as the most immediate promise of relief. We commenced giving him large draughts of castor oil, purgative glyster, and put him in the warm baths. And here I may observe that the first alarming symptom which showed itself to me was the insensibility of his lower bowels to the stimulus of the injections. Nevertheless, we were in no apprehension, but that the means then in use, if persisted in, would ultimately relieve him. Under this idea Dr. H. went home and I remained with him. He became somewhat easier after the first bath and fell into a slight doze, from which, however, he was soon aroused by a return of pain; for which the bath was again used, the oil in large doses repeated, and the glyster again resorted to, nothing, however, making any impression on his bowels in the way of evacuations.

It is needless to go through the long details of repeated and increasing sufferings. Suffice it to say, that between nine o'clock at night and the ensuing morning he had swallowed four large portions of castor oil, two ounces of Epsom salts, and sixty grains of calomel, besides the exhibitions of innumerable glysters of different sorts, and the almost constant use of the bath, sometimes warm and then almost hot. These means having entirely failed in producing the wished-for evacuations, and the pains continuing to increase, while his strength was gradually failing, I sent for Dr. Hunter again and was anxious to avail ourselves of further aid by calling in the assistance of Drs. Abernethy and Harvey, but I regret exceedingly that neither of these latter gentlemen were in town. Dr. Hunter came about sunrise, at which time our patient's sufferings were at their highest pitch of agony; his system was sinking under their influence and his own fatigue in rising so frequently to the bath. We at once determined it inadvisable to persist longer in the attempt to open his bowels, but to endeavor immediately to lull his sufferings and recruit his exhausted system. With this view, opium in large quantities and in quick succession was administered. Hot brandy toddy with peppermint and hartshorn, and without them, was exhibited liberally; mustard poultices applied to his abdomen and to his extremities, and shortly afterward a large blister to his bowels—but all in vain! His pulse continued to decline, his strength went with it, his extremities grew cold, his breathing became short and difficult, and his end was obviously fast approaching. He retained his senses without the slightest interruption until a half-hour before he died, frequently inquiring if nothing more could be done, and apparently fully conscious of his approaching dissolution, which took place about nine o'clock on Tuesday morning, after twelve hours of indescribable agony, such as I have rarely witnessed.

Progress of Medical Science.

Children's Foods. — The effects of foods upon infants has been investigated by Russow in Oldenburg Hospital. Some infants were nourished exclusively at the breast and others were given a mixed diet. At the end of fifteen days the average weight of the first class was 3,564 grams and of the last class 3,255 grams. At the end of the year the infants nourished exclusively at the breast weighed on the average 9,930 grams, and those on a mixed diet 8,480 grams, showing a difference of weight of 1,450 grams. The breast-nourished infants increased 150.7 per cent. of their weight at fifteen days, and those of the mixed diet, 140.7 per cent. Camerer shows that in the middle of the year breast-fed children were heavier, but concludes that whatever the nourishment during the first year, nevertheless all children at the end of the year reach about the same weight. Camerer gives about fifty individual cases, tabulating weights by weeks, and there is no evidence of the effects of differences of food, judging from the compared results at the end of the first year. If anything the results favor artificial foods, at any rate so far as their weight-giving properties are concerned. —*American Journal of Psychology.*

Parasites of Malarial Fever.—Dr. Ziemann (*Centralblatt für Bakteriologie*, Abth. i., Bd. xx., Nos. 18, 19) gives the results of his observations on the blood of fourteen persons suffering from agues of home origin and of seventy with acute and fifteen with latent forms of tropical remittents contracted in the Cameroons. The details of the growth of the amœboid forms appearing in the red blood corpuscles at the commencement of the hot stage, undergoing pigmentation and nucleolation, and finally, toward the end of the cold stage, sporulation by fission into two or ten or even sixteen separated nucleated cells or resting spores, is clear and interesting. He could neither verify nor refute, though he was inclined to doubt, Golgi's statement that tertian and quartan agues were marked by different forms of the parasite, nor Mannaberg's as to the quotidian and tertian; for his German cases were tertian only, and his African quotidian or irregular. He recognized two only—a larger in the European cases, and a smaller in the tropical; this was mostly ring shaped, and underwent subsequent development in two directions—either (*a*) sporulation as the European, or (*b*) into a large endoglobular cell, spherical, semilunar, or with handle-like protuberances.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 30, 1898.

THE ARMY AND THE QUARANTINE.

IT is quite evident, in view of the imminent danger of yellow fever entering our ports by the government transports from Santiago and elsewhere, that our quarantine regulations should be most rigidly enforced. We have had several scares already, and the fears of the public have been allayed only by the prompt and energetic efforts of the health authorities at the different ports of entry. The laxity of precautionary measures at the front and lack of forethought in selecting safe and proper transportation have been lamentably manifested in the deplorably filthy condition of the *Seneca*, which arrived a few days ago in New York. It would have been thought to be impossible that such a state of affairs could exist, save that the shameful demonstration to the contrary was so clearly made. Such a disgraceful object lesson cannot be studied too thoroughly to awaken us to the possibility of its repetition, especially in such times as these, when danger from a waiting pestilence threatens us almost daily from infected quarters. The medical department of the army has often asserted, with becoming pride, that it was abundantly able to care for the sanitary condition of our troops; but what excuse can now be offered for the *Seneca*, crowded with sick and wounded, without adequate surgical attendance and without suitable medical supplies? That this should be possible under such apparently well-organized supervision gives a new cause for alarm, which is as reasonable as it was unexpected. Either the department in question is too much hampered by restrictions in the performance of its bounden duties, or else it is incompetent rightly to comprehend the real gravity of the situation.

In any event, suspending judgment while the attempt is being made to fix the blame of neglect where it should rightly belong, it is quite plain that the present methods of organization are by no means what they should be, and the authorities who are thus responsible for the proceeding cannot claim that confidence from the public which otherwise they would have enjoyed. Official etiquette and red tape may hinder the prompt performance of obvious duty, but the public looks at the result and judges accordingly.

Fortunately in the present dilemma we need not look to the army department alone for guarantees of safety. The Marine Hospital service has been and is doing splendid work in all the ports where it has jurisdiction. It has demonstrated its right to be and to do on many former occasions, but on none more clearly than on the present one. We have every belief that Surgeon-General Wyman will rise to his opportunities and prove more directly than ever before the real necessity of a national quarantine law which, by its breadth, strength, and general effectiveness can give the greatest possible safety to the largest districts of country.

THE WOUNDED AFTER SIBONEY.

A DETAILED description of the care of the wounded after the battle of Siboney, as given in a recent issue of *The Sun*, casts some very severe reflections on the war department for its shameful neglect of duty in preparing for and in meeting the emergencies of the hour. If the report is true, and there seems to be no good reasons for doubting it, the army medical department appears in a very unenviable light. It is said that there was a total lack of everything necessary for the proper care of the stricken soldiers. Why this was so it is hard to explain, especially in view of the fact that the war department has constantly declared, in declining voluntary assistance from charitable organizations, that it was abundantly able to cope with any possible emergency in the field. And yet this is the result:

"When the wounded came in, the needs of the hour were overwhelming. The situation cannot be described. Thousands of our men had been hurried to the front to fight. It was well understood that it would be a hard fight. The dead would need only burial, but the wounded would need care. And yet, with the exception of a few stretchers, no preparation had been made—neither cots nor food, and practically no bandages for wounds. Is it strange that surgeons were desperate and nurses distressed?"

Farther on the correspondent says: "It was evident that the medical department of the army had failed absolutely to send hospital supplies, or by this time they would have been landed. On the one hand, it was pitiful. On the other, it was negligence that could have been the result only of incompetence."

The boasted hospital facilities are thus described: "The wounded were carried back from the fighting-lines on stretchers, and laid on the ground to wait until the surgeons could reach them. Many were soon beyond the need of surgical treatment. There were four divisions of the army, and each division was supposed to have its hospital. But as a matter of fact there was but one, the first division hospital of the fifth army corps, under Colonel Wood. There were five surgeons, a hospital steward, and twenty assistants, to care for the wounded—several hundred. They had a number of operating-tables, a small supply of medicines, but few bandages and no food for sick or wounded men. It was comparatively easy to get supplies from the *State of Texas* ashore to the hospital here—but there was no transportation to get them to the front."

Fortunately for the poor men, there was sufficient of

outside aid from the Red Cross and its supplies to balance neglect of preparation in other quarters. Said one of the medical officers, in the desperation of his helplessness: "God knows what we should have done here without the help of the Red Cross—your ship, your surgeons, and your nurses. And there is no other help for us at the front. Our wounded up there must have food, bandages, anything you can let us have in the line of hospital supplies."

It is right and proper that the surgeon-general should resent any interference with his prerogatives, but he should not directly invite it by making possible such a condition of affairs as here described.

ULCERS OF THE DUODENUM.

The occurrence of duodenal ulceration from certain causes has long been recognized, and the fact that we may have in the duodenum ulceration of the same kind as the so-called peptic ulcers in the stomach is well known. The behavior of these ulcerations is a matter of great interest and importance in abdominal surgery. A Russian surgeon, Dr. Wanach, in a communication to the *Archiv fur klinische Chirurgie*, vol. lvi., No. 2, gives a review of the cases reported by various surgeons, and also an interesting account of a successful operation by himself.

We are struck by the fact that in no case in which an operation was done was the diagnosis made as to the site of the perforation for the symptoms of which the operation was undertaken. The diagnosis of peritonitis from perforation is of course simple enough, but to locate the perforation before operation is another matter. In many of the recorded cases the diagnosis was made of perforation of the vermiform appendix, and the error is quite comprehensible. It seems to be a pretty uniform symptom to have the pain, at the time when the perforation occurs, referred to the right side and usually high up, though the localization may be in the umbilical region, and thus, if there is much distention, leave us in grave doubt. If the pain is on the right side, we shall almost certainly discover tenderness there also, and the region is near enough to that of the appendix to justify us in supposing that that structure is responsible for the symptoms, because we know what a large proportion of cases of perforative peritonitis do have their origin in it. The patient in the early stage of an acute peritonitis is usually in too anxious a condition to help us in this matter of localizing the pain.

There is one sign of differential diagnosis between appendicitis and perforation from some other cause which we do not commonly see mentioned, and that is that pressure over the inflamed appendix will elicit tenderness in that region and pain referred to the epigastrium. This is not always noted, but in some cases it might be of service in enabling us to decide upon the diagnosis. This sign would not be present in gastric or duodenal perforation. We might have the epigastric pain, but not the tenderness on pressure in the iliac fossa. Unless we see the cases early enough to have our attention drawn definitely to the right side of the abdomen, we must proceed in our operative work upon general principles, if we are to operate with any prospect of success.

Perhaps the most important aid that we can get will come from a very careful clinical history both of the onset and course of the acute trouble and of any disorder of the stomach or intestines in the previous history of the patient. We may get a history pointing toward gastric ulcer, and if an operation is done upon any of these cases we should, in the natural order of things, look for a perforation of the stomach before examining the deeper parts to find a suspected duodenal perforation. The surgeon ought to get valuable aid from the physician in this class of cases, for it is upon the latter that we must depend for our accurate histories and intelligent observation during any previous illness that the patient may have had.

The cases of ulcer of the duodenum so far seen are pretty uniform in their characteristics, and the condition described by those who have seen such cases operated upon for perforation has been that of an indurated thickened area, with a perforation of variable size, but usually round, in the centre of the area, and the site of the perforation has been very commonly at or near the apex of the curvature of the second portion of the duodenum, at a point at which the gastric contents have not lost their acid digestive power by becoming mixed with the bile and pancreatic secretion.

The question of what to do with the perforation, when we have found it, is not so simple as it might seem. If we merely invert the edges by the usual method of intestinal suture, we run the risk of suturing through soft necrotic tissue with the consequent danger of infection and giving way of the sutures; and if we attempt to excise the whole ulcer we are apt to encounter great difficulty in placing our sutures and getting apposition, on account of the depth at which we are working. Of course, if the ulcer has perforated the intestinal wall at a part not covered by peritoneum, a retroperitoneal abscess is promptly developed, and the directions in which such an affair can travel are limited only by the patient's ability to stand the inroads upon his vitality and the involvement of other organs.

In one of the reported cases in which it was not possible to reach the perforation so as to suture it, the operator simply sewed the neighboring omentum, stomach, and intestine together over the location of the perforation, and the patient recovered. Most surgeons, however, would adopt such a measure only as one fraught with great risk, and would probably prefer to trust to a drainage tube and packing for the first part of the treatment.

It has been the universal experience that it is better to treat the abdominal wound in these cases by packing and drainage, chiefly on account of the infected condition of the whole abdominal cavity by the time the operation is done, and the greater security which such a method gives when we are dealing with tissue of such dubious vitality as that in the edge of an intestinal perforation. The question of irrigation is to be decided upon the same general principles which govern all abdominal work.

The whole subject of the surgical treatment of such ulceration is only in its infancy, and every carefully recorded observation helps to add to our knowledge of a necessarily obscure condition. We must hope that by careful observation of such cases by the surgeon and by careful investigation by the pathologist, we may in the future be able to recognize the condition present with sufficient promptness to render important aid in an increasing proportion of cases at best very grave.

MOSQUITOES AND MALARIA.

The theory that certain diseases may be conveyed by means of insects is not a new one. Linnæus was among the first to make the suggestion, although his views in this respect gained no foothold. Dr. Drake and Sir Henry Holland also drew attention to its probability. Latterly many investigators have endeavored to show that the mosquito is indirectly instrumental in the production of many diseases, and especially in that of malaria. Dr. Charles Finlay, of Havana, in 1881 submitted some papers to L'Académie Royale des Sciences Médicales in Belgium, tending to prove that the mosquito under certain conditions may act as the transmittor of yellow fever, and has repeatedly since that time written in support of this belief.

Quite recently Dr. Patrick Manson, who for many years has held the belief that the mosquito may "act as the intermediary host of filaria sanguinis hominis," has stated his opinion that the mosquito plays the part of the extracorporeal host of the plasmodium malariæ. Koch, who has just returned from East Africa, where he has been studying the clinical and etiological aspects of malaria under peculiarly favorable circumstances, is in agreement with these views. He bases this agreement on the ground that mosquitoes are always prevalent wherever malaria prevails, and he mentions one locality in which, mosquitoes being absent, there is no malaria, although the conditions are otherwise favorable to its production. Bignami last year published a paper in which almost identical conclusions were drawn. Referring to the observations of Smith and Kilborne, he drew attention to an example of a disease of the blood due to an intracorpuscular parasite and inoculated into cattle by a suctorial insect, and went on to say: "Malaria behaves itself with regard to man as if the malarial germs were inoculated by mosquitoes." As long ago as 1893 Marchiafava repeatedly asserted in private his belief in this mode of transmission of malaria, but he did not publish this view, as what he regarded as a positive demonstration was wanting. Now, however, the contention that the malarial poison is disseminated by the mosquito is supported by facts which are practically as convincing as those which can be adduced in favor of any other theory as to its cause. The question as to how the fever is contracted is a most important one, for once it is solved the way will be paved for a rational prophylaxis of malaria.

THE "SENECA" CASE.

If the daily papers are to be believed, there would appear to be a disposition on the part of the army medical authorities to shift the responsibility of the *Seneca* scandal on to the two acting assistant surgeons who were assigned to the ship to care for the wounded. It is given out, as though that fact completely relieved the military authorities of all blame, that these young men were not regular army surgeons, but only "contract doctors"—civilians hired by the month to take care of the soldiers. But it may be asked why these doctors were hired by the medical department if they were incompetent, and also why the lives of so many people were intrusted to their keeping; and again, if they were so inexperienced, why some one did not inspect the vessel and the stores to see if everything was as it should be. The responsible persons cannot be exculpated by sneers at civilians, and we cannot believe that the surgeon-general will allow himself to be turned from his avowed purpose to fix the responsibility by any such puerile excuses. Some one who was in authority at Siboney when the wounded were transferred to the *Seneca* from the *Relief* is responsible for this wretched affair. The two acting assistant surgeons may have been and probably were inexperienced, but inexperience is no crime; the crime is rather in intrusting vital matters to inexperienced persons. The "contract doctors" are certainly not to blame for the *Seneca* scandal.

News of the Week.

The Medical Club of Berlin.—We have received a courteous communication from the "Aerztlicher Club von Berlin," informing us that foreign physicians are granted free admission to the clubrooms. Physicians from abroad, resident for a certain period in Berlin, will be welcomed as temporary members upon introduction by a regular member. The club is in the Lindengallerie, Berlin, W.

Alfonso XIII., the little King of Spain, in addition to his other troubles, is now suffering from an attack of measles.

The Governor of Santiago a Physician.—Gen. Leonard Wood, formerly colonel of the Rough Riders, has been appointed military governor of Santiago. The appointment must be regarded as a peculiarly happy one, for one of the first problems that confront us is the sanitation of the city, and General Wood's medical training and experience will enable him to supervise this work with intelligence and good effect.

Abandonment of Camp Alger.—There is some discussion concerning the advisability of abandoning Camp Alger because of the pollution of its water supply. Typhoid and malarial fevers have prevailed in the camp from the date of its establishment, and, indeed, prevailed in the country thereabout for years before the site was selected. This and the fact that the water supply is wholly inadequate lead naturally to a query as to why the camp was ever established at that point.

Death of a Centenarian.—Mr. Elijah Glenn died a few days ago, in Newark, N. J., within a few days of his one hundred and second birthday. He was born in Maryland, August 7, 1796.

The Yellow Fever.—The latest reports from Santiago show no change in the situation there as regards the yellow fever. Despite the filthy condition of the streets, there is but little fever within the city. The new governor, Gen. Leonard Wood, may be depended upon to do everything possible in the way of cleaning the city, and it is believed that a widespread epidemic among the troops may be averted. The type of the disease continues mild, the mortality being very light. Out of 1,000 cases of yellow, malarial, and typhoid fevers and measles reported up to July 25th, there were only three deaths, according to the Siboney correspondent of *The Sun*. Dr. Lesser, of the Red Cross Society, and the four nurses of his staff have recovered. There is no case of the disease in this country, so far as known at the present writing. An epidemic is reported from Merida and other coast towns in Yucatan, brought probably from Cuba by the blockade runners.

Food for the Klondike.—It is reported that a food shortage in the Klondike next winter is greatly feared by those conversant with the conditions in that region. There are many people there without work and without money, and it will be necessary to furnish them with transportation southward this summer or to feed them next winter.

Firing on the Wounded.—Mrs. John Addison Porter, wife of the secretary to the President, who is with the Red Cross at Santiago, has written to her husband a letter describing the events before the surrender, extracts from which have been made public. She confirms the stories of Spanish barbarity in firing on the wounded, and says that in several instances wounded men were shot dead as they lay in Red Cross litters on their way to hospitals. This firing was so continuous that the surgeons performed operations by moonlight, being afraid to light candles or lanterns, as Spanish sharpshooters would have picked them off.

Typhoid Fever is spreading in the Florida camps. The number of cases is not known definitely, but it has become so large that the army medical authorities have found it necessary to accept the services of Red Cross nurses, which were at first refused.

Soldiers' Convalescent Homes.—It is stated in *The Hospital* that the Italian government provides six convalescent homes for sick soldiers. The soldiers are said to be admirably housed in these homes, treated extremely well, and the homes are generally on royal property and in some cases consist of royal palaces. In addition to such convalescent homes for the private soldier—entirely maintained by the government—officers and non-commissioned officers are sent to various baths and medicinal springs in Italy at their country's expense, when their condition calls for such treatment. There is a movement in England for the establishment of soldiers' convalescent homes and also homes for dying soldiers, but the project has hardly gone yet beyond the stage of agitation.

A Hospital Cotton Bale.—The first bale of cotton of the crop of 1898 was sent by H. and B. Beer, of New Orleans, to President McKinley as a contribution to the United States hospital fund. The President forwarded it to Lieutenant-Colonel Kimball, of the quartermaster's department, at the army building in this city, with instructions to have the Cotton Exchange take charge of its disposal. It was sold at auction to the president of the exchange for $500, which sum had been raised by the brokers for this purpose, and the purchasers sent it back with a check for $500 to Lieutenant-Colonel Kimball, that it might be again sold. It is thought that the bale, like a similar bale during the civil war, may now start on a tour of the principal commercial exchanges of the country. It is likely to be sent next to the Boston Chamber of Commerce. The cotton, at this sale, brought about $1 a pound.

The Mississippi Valley Medical Association.—The twenty-fourth annual meeting of this association will be held at Nashville, Tenn., October 11th–14th, under the presidency of Dr. John Young Brown, of St. Louis, Mo. The annual addresses will be made by Dr. James T. Whittaker, of Cincinnati, on medicine; and by Dr. George Ben Johnson, of Richmond, Va., on surgery. Dr. Duncan Eve, of Nashville, is chairman of the committee of arrangements. Titles of papers to be read at the meeting should be sent to the secretary, Dr. Henry E. Tuley, 111 West Kentucky Street, Louisville, Ky., as early as possible to insure a good place upon the programme. Reduced rates on all railroads will be granted on the certificate plan.

Dr. Fenton B. Turck, of Chicago, writes that he has been invited to give a demonstration before the forthcoming meeting of the British Medical Association of his methods of diagnosis, treatment, and experimental work in diseases of the stomach and intestines. He will also read papers by invitation as follows: "A New Method of Treatment of Gastric Myasthenia," and "A New Operation for Gastrostomy and Curettage for Carcinoma of the Cardia."

The Cumberland County (N. J.) Medical Society convened at Hotel Cumberland, Bridgeton, July 12, 1898. The meeting was called to order by Vice-President Dr. J. B. Ware, of Bridgeton. A paper on "Nephritis in Children" was read by Dr. T. G. Davis, of Bridgeton. Dr. H. W. Elmer reported as delegate to the American Medical Association. Dr. L. L. Hand, of Leesburgh, presented an exhaustive report of the meeting of the State Medical Society.

Dr. John Carling, of this city, has sailed on the *Olivette* for Santiago, with orders to report to General Shafter. He will probably be assigned to duty in the yellow-fever camp.

A Prize for Clean Teeth.—A man in Maine, it is said, has offered a number of small prizes to the school children in his town who take the best care of their teeth during the summer vacation.

Poor Santiago!—Spanish rule of Cuba was notoriously bad, but it had at least one redeeming feature. Among the many articles, the importation of which into the island was prohibited by law, were medical preparations of unknown composition. Under American rule this prohibition has been annulled, and now the natives will enjoy the opportunity for unlimited indulgence in the liver ticklers, vegetable compounds, pile remedies, and other delectable nostrums that are swallowed in such generous quantities by the people of this free land.

"The Women's Medical Journal."—In the recent failure of the Recorder Publishing Company of Toledo, Ohio, the *Women's Medical Journal* was included in the assets, and was bought in and will be operated by Miss M. L. Hockedern and others. The present editorial staff, it is understood, will retire.

The German Otological Society held its annual meeting in Würzburg, under the presidency of Professor Bezold, of Munich, on May 31st, and June 1st and 2d. The meeting was attended by eighty-five otologists, of whom six were Japanese. It was voted to erect a memorial to Professor von Tröltsch, who taught in the University of Würzburg from 1864 till his death in 1890. The next annual meeting will be held in Hamburg.

The Health of New York State. — According to the bulletin of the State board of health, just issued, the daily average mortality during the month of June was 288, which is 6 below the daily average of that month for the past ten years. The death rate was 16 per 1,000. Compared with June of last year, the deaths were fewer in every one of the sanitary districts, the decrease being mainly in the infant mortality, although there were also fewer deaths from zymotic and acute respiratory diseases among adults. Diarrhœal diseases caused 375 deaths, which is only half the usual mortality for June. Diphtheria caused 175 deaths, or one-half the number for June, 1897. Whooping-cough caused 111 deaths, double that of last June. Cerebro-spinal meningitis is also very much more prevalent than a year ago, 110 deaths being reported from it, the increase being mainly in the maritime district. The number of deaths from tuberculosis was nearly the same as in June of last year, namely, about 1,000, but it was 120 less than the figures for May.

The University of Odessa.—A medical faculty is about to be constituted in the University of Odessa, and will be formally opened next autumn. Dr. Podvysovski, of the University of Kieff, and editor of the *Russkii Arkhiv*, has been called to the chair of pathology in the new faculty, of which he has also been appointed dean.

Leprosy on the Baltic.—The publication of the official report concerning the prevalence of leprosy in the province of Memel threatens to ruin the business of hotel keepers at the seaside resorts on the shores of the Baltic Sea. The authorities at these places are making strenuous efforts to convince the public that no leper ever saw the waters of this pleasant sea.

The Tri-County Medical Society of Ford, Iroquois, and Vermilion counties (Ill.) held its annual meeting at Paxton on July 6th. Twenty-six members were in attendance. The annual election resulted in the choice of Dr. J. Y. Campbell, of Paxton, *President;* Dr. R. Hemala, of Onarga, *Vice-President;* and Dr. Leroy Jones, of Hoopeston, *Secretary and Treasurer.* Papers were read by Drs. Wylie, Mason, McClintock, Peirce, Strauss, and Lovell.

A Woman Druggist.—A young woman of Keyport, N. J., recently took the written examination before the State board of pharmacy for a certificate permitting her to practise as a registered druggist and pharmacist in New Jersey. If successful, she will be the first woman pharmacist in the State. Forty-four men came up for examination at the same time.

Dr. J. J. Ulloa, of San José de Costa Rica, has come to this city in the capacity of consul-general of Costa Rica. He was recently secretary of state of that country. Dr. Ulloa was graduated in medicine from a New York school about twenty years ago, and served the regular term as interne at St. Vincent's Hospital.

Death of Professor Rokitansky.—Dr. Karal Freiherr von Rokitansky, a son of the great pathologist, died at Gratz, on June 20th, at the age of fifty-eight years. He was born in Vienna, and received his medical degree from the university there in 1865. He became privat-docent in midwifery and gynæcology at the University of Vienna in 1872, and extraordinary professor of gynæcology at the same university in 1880. In 1892 he was called to the University of Gratz to fill the chair of midwifery and gynæcology. He had suffered for some years from the chronic nephritis which was the cause of his death.

Comparative Effects of Bullets of Different Patterns.—A correspondent of *The Sun* at Siboney describes the results of certain experiments made by Major Lagarde, who is in charge of the hospitals at that place, to determine the penetrating power of the bullets used on both sides in the fights that have taken place between the Spanish and American troops around Santiago. The bullet of the Mauser rifle of the pattern of 1895 penetrated 32.5 inches of yellow pitch pine; the Mauser of 1896, 32.54 inches; and that of 1897, 35.125 inches. The Krag-Jorgensen of 1898 penetrated 26.125 inches, but the Springfield rifle could send a bullet only six inches through the same wood.

The Ambulance Ship "Solace" sailed from this port recently. While at the navy yard she had an additional ice machine installed, and was supplied with a carbonater and an *x*-ray apparatus. She will go to Key West and take on board all the naval sick or wounded in the hospitals or on the vessels in port, and will then sail around the island of Cuba, taking on board the sick and wounded from the blockading vessels, and leaving them ice, fruit, delicacies, and stores for the sick. As soon as she receives her complement of sick and wounded, she will bring them to one of the Northern naval hospitals.

Dr. Frederick L. Benton, of Brooklyn, has been appointed assistant surgeon in the navy, and is assigned to the cruiser *Brooklyn*, Commodore Schley's flagship.

The Transport "Olivette" sailed on Wednesday for Santiago. Her cargo is chiefly composed of hospital stores and delicacies for the benefit of the sick and wounded at El Caney and Santiago, but, in addition, she is carrying tents and clothing for the soldiers in camp in and around Santiago. The latter is much needed, as the men—who were for the most part on first landing in Cuba clothed in their ordinary thick regimentals, which they were forced to discard—are in a woefully ragged condition. The *Olivette* will carry an army ambulance corps, with surgeons and thirty-four nurses, twenty of whom are colored.

Scorbutus so infrequently enters our ports of recent years that the arrival of a scurvy-infected vessel a short time ago, four months out from Java, is of sufficient moment to cause comment.

The Army Hospital Ship "Relief," with one hundred and twenty-five sick and wounded aboard, arrived in New York harbor a week ago. On Tuesday about half her patients were transferred to Bellevue Hospital, and the remainder were taken to St. Peter's Hospital and the Long Island College Hospital in Brooklyn. The voyage from Siboney was marked by magnificent weather, and the patients bore the journey remarkably well. There was no case of fever aboard, and the sanitary arrangements more than fulfilled expectations. The *Relief* when off Santiago took on board two hundred and sixty-six sick and wounded, of which number many were transferred to the *Seneca* and other ships, and fourteen died. All the wounded were in the large wards on the main and upper decks. The surgeons on the *Relief* are loud in their praises of her efficiency as a hospital and ambulance ship, and say that, excepting for a few details, notably the insufficiency of water-closet accommodation, she is almost perfect. The opinion in regard to the nature of the wounds inflicted by the Mauser bullets coincides very closely with that of the British surgeons in respect to the injuries inflicted by the ordinary Lee-Metford bullets in the recent campaigns in the Soudan and the Indian frontier war. One somewhat curious feature in connection with the engagement at Santiago is the fact that the majority of the injured were hit in the lower extremities, the explanation of which appears to be that they were wounded by falling bullets fired from a long range. The success attending the application of the *x*-rays in locating bullets has been most gratifying, and it may be said that their practical use has been fully demonstrated. Several major operations were performed on the *Relief*. Taking into consideration the fact that only those most severely injured were brought aboard to be treated, the results were extremely good. Under the modern conditions of naval and military warfare, hospital ships are a necessity, and the experience gained during the present war will be of the greatest use in the direction of evolving the perfect hospital ship.

Sir William Henry Broadbent has been appointed physician extraordinary to the Queen, in the room of the late Sir Richard Quain.

The American Academy of Medicine is said to have a membership of seven hundred and sixty-eight fellows, sixty of whom were admitted in the present year. It has been voted that those joining the society hereafter shall pay a yearly due of $1 in addition to the initiation fee of $5. Heretofore there have been no annual dues, although most of the members were subscribers to the journal of the transactions.

A Wheel Struck by Lightning.—An Irish physician was riding a bicycle near Queenstown recently, when lightning struck his wheel, wrecking it beyond repair. The rider was bruised a little by his tumble but was otherwise uninjured.

The Summer Corps of the Board of Health.—Thirty-eight summer inspectors, the greater number of them from the corps of school inspectors, have been appointed to serve from now until September 10th. Their special duties are to instruct mothers in the care of infants during the heated term and to treat any sick children whose parents cannot afford the services of a physician.

Pure Drinking-Water.—The committee on sanitation of the National Relief Commission, in Philadelphia, is engaged in a most commendable effort to introduce methods of purification of all the water supplied to our troops. It has issued a brochure, setting forth the advantages of boiling and subsequently aerating drinking-water. In view of the epidemics of typhoid fever which prevail at several of the camps, to the discredit of the medical department of the army, the missionary enterprise of this committee is most timely. Dr. M. S. French is the general secretary of the relief commission, and Dr. E. O. Shakespeare the chairman of the committee on sanitation. The office of the commission is in the Drexel Building, Philadelphia.

Foreign Practitioners in Berlin.—The police authorities of Berlin have issued an order which is of special interest to foreign physicians and dentists. It is permitted to display the title of "Arzt" (physician) upon a "shingle," provided it is at the same time designated where that title has been obtained, *e.g.*, "N——, Doctor of Dental Surgery of Chicago," etc. The native medical men have taken stand against this order upon two grounds: First, because German physicians have not the same rights in other countries, especially in Switzerland; and secondly, because it is a useless order in Germany, where, in fact, anybody may practise the healing art. The profession is, however, making strenuous efforts to terminate by legal means and measures this freedom of practice, but the success of such endeavors is at least problematical. Many persons of political influence have come out against the physicians, maintaining that every one has a right to select his own executioner, and may physic himself to health or to death as he may elect or as chance may decide.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Thirty-Ninth Regular Meeting, Held on Friday, April 1, 1898.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

Some Remarks on Diphtheria Toxæmia and Immunity in Horses.—DR. H. M. BIGGS read a paper with this title. In reply to a question by Dr. George L. Peabody, as to whether the serum retained its antitoxic properties unchanged for an indefinite period, and whether freezing harmed or weakened the serum, the speaker said that when the serum was kept in bottles which were almost completely filled its antitoxic properties remained comparatively unchanged for months, even at the laboratory temperature. Experiments had shown that there was rarely a loss of over ten per cent. in antitoxic power under such circumstances. When the bottles were only partially filled, however, and contained a considerable amount of air, the loss of strength might be much greater, amounting in some instances to twenty or twenty-five per cent. The rule of the New York health department was that after six months the unused serum was replaced by a fresh product. In that length of time it usually showed some precipitation, becoming cloudy and milky, but in spite of this its actual antitoxic properties were not much affected, and it was perfectly safe to administer it, so far as was known. Freezing, Dr. Biggs said, did not affect the strength of the serum, or at least not to any appreciable extent. In reply to a question by Dr. Dana, he said that diphtheria antitoxin administered per os seemed to have little or no effect.

DR. J. W. BRANNAN said that at the Willard Parker Hospital during the past winter the serum which was employed was first filtered through cotton, and this practice had resulted in largely reducing the number of cases in which rashes appeared after the administration of the remedy.

DR. BIGGS said the cause of these rashes was still a mystery. One bleeding from a certain animal might produce a rash in a large percentage of the cases in which the serum was used, and another bleeding from the same animal a month later might produce very few rashes. Again, the serum from one animal might produce many rashes, while that from another animal might produce very few. Roux was formerly of the opinion that the serum from black horses was much more likely to produce rashes than that taken from horses of other colors; experience in this city had not borne out that view. It was more likely that the rashes were due to some individual peculiarity of the animal from which the serum was extracted. The irritant was in the serum, not in the antitoxin. It had been suggested that it might be related to certain abnormal conditions in the animals, analogous perhaps to lithæmia in the human being. In reply to a question Dr. Biggs said that a toxin unit was the amount of toxin which was required to kill a guinea-pig weighing two hundred and fifty grams, in from three to five days, and an antitoxin unit was one hundred times the amount of antitoxin that was required to neutralize a toxin unit.

DR. T. MITCHELL PRUDDEN said that a very interesting feature of the paper was the great tolerance shown by certain animals to the administration of the toxin, and the fact that it produced no effects on the nervous system of such animals.

DR. W. GILMAN THOMPSON said that the paper had a very important bearing on the general theory of immunity, and seemed to add to the difficulties of that subject rather than to simplify. The strength of the serum extracted from horses was apparently not diminished by repeated bleeding, and it was difficult to understand why some animals could resist such large doses of the toxin.

DR. BIGGS said he was unable to explain the extraordinary natural immunity possessed by some animals. In one instance, for example, eighty times the minimum dose of the toxin which had proved fatal to one horse was injected into another horse, and produced scarcely any constitutional disturbance; increasing doses were given until eighty thousand toxin units could be injected at one time. In spite of these enormous doses that animal never produced a high grade of antitoxin. On the other hand, in the very susceptible animals small doses (perhaps five toxin units) brought about a decided reaction, but such animals never produced a very high grade of serum. The varying degrees of immunity possessed by the animals was probably due to the natural resistance of the tissue cells, and had an analogy in the condition which was found in human beings, of whom, out of a number exposed to the same infection to the same extent, some might show its effects to a virulent degree, others to a very mild degree, while still others might escape entirely.

DR. THOMPSON said it was hard to explain the permanence of the antitoxin in the blood, for the latter, as a rule, promptly eliminated all foreign bodies.

DR. BIGGS said that when the injections of toxin were discontinued, the strength of the serum withdrawn from such an animal diminished quite rapidly. In reply to a question of Dr. A. H. Smith, as to whether efforts had been made to isolate the antitoxin from the serum, he said that very extensive experiments had been made in this direction, but thus far they had not proven very satisfactory. It could not be filtered out. It might be preserved in a dry condition, if kept from the air and light and in sealed bottles.

A Case of Cancer of the Tonsil and Pharynx.—The patient, presented by DR. JOSEPH D. BRYANT, was a man, fifty years old, a laborer. His family history was negative. The patient had had rheumatism for the past fifteen years; his personal habits were good, excepting that he had long been an excessive smoker. One year ago he noticed a small movable tumor—as he called it—near the angle of the jaw, which gradually increased in size. It was circumscribed, and was neither tender nor painful. He stated that he had had no throat trouble, and it was not until the early part of February, 1898, that he sought medical advice, and then on account of a severe pain which commenced in his throat and radiated up to his left ear. He consulted Dr. Ed Ferguson, of Troy, N. Y., who found an ulceration of the pharynx and tonsil which he regarded as malignant, and sent the man to Dr. Bryant for surgical interference. When the patient was admitted to Bellevue Hospital on March 3, 1898, he was found to have an enlarged gland, about the size of a big English walnut, just below the angle of the jaw on the left side. An inspection of the throat showed an extensive ulceration, which had destroyed the left tonsil, a portion of the pharynx on its lateral wall, and extended into the deeper tissues down to the base of the tongue, encroaching upon that organ to the extent of about half an inch. On March 7th, under chloroform, three enlarged glands in the submaxillary space were removed through an incision extending from below the lobe of the ear and along the cutaneous border of the sternomastoid to the thyroid cartilage. The dissection was then carried downward, the external carotid was tied, and the lower jaw was divided in front of the last molar

tooth through an incision extending from near the middle of the cheek downward to the middle of the preceding incision, and removed, thereby exposing the outer wall of the pharynx. The hemorrhage following this was so persistent that it was necessary to resort to plugging in order to control it. The tampon was left undisturbed for forty-eight hours. During this interval the patient was as comfortable as could be expected, his temperature never going above 100.2° per rectum, nor his pulse above 80. After forty-eight hours chloroform was again administered and the operation completed. The tampon was removed, the tissues were drawn aside, and the muscular structures divided down to the aponeurosis of the pharynx. The entire diseased tissue was then cut away. The lingual nerve was saved by dissecting it loose throughout its entire length and drawing it out of the field of operation. Another point of interest was a very large pharyngeal vein which was found lying in close contact with the outer wall of the superior constrictor. Since the second operation, which was done on March 9th, the patient had progressed very favorably. His temperature never rose above 101.8° F. (in the rectum), nor his pulse above 104. He was out of bed on the sixth day. The pathologist reported that the case was one of epithelioma. The growth probably originated in the tonsil, and gave rise to secondary involvement of the tongue, pharynx, and glands.

Dr. George L. Peabody referred to a case that had come under his observation in which a large mass of cancerous glands in the neck, which had been regarded by the surgeon as the primary focus of the disease, was found on further investigation to be secondary to an epithelioma in the mouth. In another case a patient who presented himself at the New York Hospital to have an enlarged gland in the neck removed was found to have a large epitheliomatous ulcer in the mouth, of which he was unconscious.

Dr. George F. Shrady said that epithelioma of the tongue, of secondary origin, was a comparatively rare condition. Personally, he could recall but two such cases. One of them was the case of General Grant, in which the disease commenced in the pillars of the fauces and secondarily involved the tongue and subsequently the glands in the neck. The speaker said he thought Dr. Bryant's plan of tamponing the wound at the first operation and completing the work later was an excellent expedient.

Dr. Bryant said that in the case presented the disease had advanced to such an extent that he was at first inclined to regard it as hopeless so far as surgical interference was concerned. By tamponing the wound after removal of the jaw and completing the operation at a later stage he was enabled to remove the diseased tissue much more thoroughly, with less hemorrhage and less danger of infecting the wound.

A Case of Hysteria, with an Interesting Temperature Chart.—This case was reported by Dr. Andrew H. Smith. The patient was a female, a trained nurse, with an unimportant family and personal history. During the three weeks previous to her admission to the Presbyterian Hospital she had suffered from fever and pain in the side and limbs, her symptoms being first attributed to malaria and afterward to grippe. Four days previous to her admission she began to vomit after taking nourishment. After two days her vomiting became almost continuous; she never vomited any blood, but complained of pain and soreness in the epigastrium. Upon her admission to the hospital on February 16, 1898, the patient's most prominent symptom in addition to the vomiting was the temperature. On February 16th, this ranged from 98° F. at 10 A.M. to 102° at 4 P.M., then rapidly fell to 99 F. On the following day it ranged from 97° at noon to 104.5° F. at 8 P.M., and then within two hours fell to 100° F. On the following day it ranged from 97.5° at 8 A.M. to 104.5° F. at noon, falling to normal within four hours. Subsequent to this date the temperature never rose above 100.5° F., and gradually became normal. In addition to her temperature and gastric symptoms the patient had certain stigmata of hysteria, *i.e.*, enormously dilated pupils, retention of urine for long periods, and an absence of the palate reflex. Nothing of importance was found in the physical examination, and no plasmodium malariæ could be discovered in the blood. Large doses of quinine had no effect on the fever. It was finally decided to try asafœtida, and under its administration the temperature rapidly dropped to normal and the vomiting ceased.

Dr. Bryant mentioned the case of a hysterical woman who had a wonderful way of getting her rectal temperature up to 108° and even 110° F., while her axillary temperature remained normal. The patient he referred to was well known in various hospitals in New York. She had a fæcal fistula, and numerous laparotomies had been performed upon her.

Dr. A. H. Smith said he had seen the patient referred to by Dr. Bryant. Among her other hysterical manifestations she frequently vomited fæcal matter which she had surreptitiously swallowed. In reply to a question the speaker said he thought that in his case the woman's gastric symptoms were not sufficiently severe to account for the vagaries in her temperature.

Dr. Charles L. Dana said he did not believe there was any such thing as true hysterical fever. Hysteria was a psychosis—a disease of the mind—and we could not by any disease of the mind raise the temperature to any marked degree. Of course, during excitement the temperature rose somewhat, but the continuous forms of fever seen in hysterical persons must be explained by some somatic complication or else were of artificial origin. The speaker said he had never seen a case of true hysterical fever, and the cases that had been reported of continuous (or more or less continuous) hysterical fever were probably something else. In Dr. Smith's case he thought the exacerbations of temperature might be attributable to the gastric disturbance or to some incidental features.

Dr. Peabody said that Dr. Dana's explanation of the fever sometimes observed in hysterical people added to the obscurity of those cases rather than cleared it up. The fever might be due to some somatic complication, as Dr. Dana had suggested, but, if so, frequently it could not be made out. The speaker said he thought he had seen cases of true hysterical fever—not continuous fever, but intermittent in character, as in Dr. Smith's case. Doubtless, in many instances these were cases of pure deception. In a case which came under his observation some years ago the patient had an axillary temperature ranging from 118° to 120° F. For a number of days the patient's method of producing this temperature remained undetected, but it was finally discovered that she accomplished it by heating a piece of brick on the stove and placing it in the axilla a few minutes before the nurse came in to take her temperature.

Dr. Robert Abbe said that, according to the chart shown by Dr. Smith, the patient's pulse never went above 88° F., even when her temperature rose to 104.5° F. Such a discrepancy, he thought, was incompatible with the usual relations of true febrile reaction.

Dr. Thompson said he felt sceptical about the existence of such a condition as true hysterical fever. A number of cases had come under his observation in which exceedingly clever methods were employed to produce an artificial temperature record. In one case, which was reported some time ago before the Association of American Physicians by one of its members,

the patient had a temperature record of 148° F., for which no explanation could be found. Of course, as an actual fact, this was a physiological impossibility. The patient, who was a clever sleight-of-hand man, subsequently was turned out of two hospitals in New York for malingering and knavery. At the Presbyterian Hospital his temperature record was 109° F., and his pulse 70. He was turned out by Dr. Thompson, who on the following day found him at the New York Hospital, where a surgeon was about to operate on him for a supposed internal injury which he claimed to have met with, and which his high temperature tended to confirm. His temperature record promptly dropped to normal when he learned that he would have to leave the hospital. Dr. Thompson mentioned another case of so-called hysterical fever, lasting eight weeks, which proved to be clever malingering. A third case was one which Dr. Peabody saw about ten years ago and reported in the MEDICAL RECORD as a case of hysterical fever. The patient was a girl who remained in the New York Hospital for six or seven weeks, with a temperature of 105° or 106° F. Dr. Thompson happened to see the patient at that time and subsequently encountered her at the Presbyterian Hospital, where she had been for over a month; she complained of pain over the spleen, had a high temperature, and was supposed to be suffering from an intra-abdominal abscess. On her being accused of malingering her temperature went down and she left the hospital. The speaker called attention to the fact that the ordinary clinical thermometer did not register above 110° F., and when the large thermometer was used, unless its position was carefully watched, the column would record any desired temperature when the instrument was held in a slightly slanting position. In conclusion, Dr. Thompson said that a belief in "hysterical fever" seemed to be in direct opposition to all known physiological laws and the phenomena of fever.

DR. A. H. SMITH said that in the case he had reported the temperature recorded was taken in the rectum.

DR. PEABODY said that with the ordinary clinical thermometer some patients were able to raise the column of mercury by squeezing the bulb of the instrument.

DR. THOMPSON stated that the true internal temperature could readily be ascertained by taking the temperature of a stream of urine as it was being passed.

A Case for Diagnosis: Hysteria or Malingering?—This case was reported by DR. GEORGE L. PEABODY. The patient was a young man, eighteen years old, a Hebrew, who, after having had some trouble with his father, left his home in Philadelphia and came to this city in search of work. While walking along the street he was seen to stagger and then to sit down on the curb. A policeman was summoned, who found that the young man was apparently unable to move his legs, speak, or hear. He was taken to the New York Hospital in an ambulance, and on his arrival there it was found that he had some control over his legs but was still unable to speak or hear. He was able, however, to write an intelligent reply to any question that was put to him in writing. Various methods of surprising him, in order to ascertain whether he was really deaf and dumb, were tried, but all were unsuccessful. A bath, with the water at a temperature of 50° F., was then prepared, and he was immersed in it and kept there until his fingers and lips were blue, and although he resisted a good deal he did not make a murmur. He was then etherized; when he had partially recovered from the influence of the ether he sat up in bed, and on being asked in a loud voice, "How are you?" he replied, "I'm all right." Within an hour he was up and walking about the ward, and had no further trouble with his speech or hearing. He was kept under observation a week and maintained to the last that he was unable to hear or speak when he was brought to the hospital, and that the ether cured him. Dr. Peabody added that in his opinion the case was one of hysteria. The patient had a number of the stigmata of hysteria, among them being anæsthesia of the pharynx and conjunctiva, and of local areas of the integument.

One Hundred and Fortieth Regular Meeting, Held on Friday, May 6, 1898.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

Cerebral Hemiplegia following Diphtheria, with Report of a Case.—DR. J. W. BRANNAN reported this case (see page 155).

DR. BEVERLEY ROBINSON said he had never seen cerebral paralysis following diphtheria. Personally he would be inclined to favor embolism rather than hemorrhage as the cause of such paralysis. In diphtheria there was a special tendency to the formation of fibrinous clots, which might remain in the right and even in the left heart for some time. During a recent post-mortem at St. Luke's Hospital a fibrinous clot was found in the right heart, which the speaker said he felt quite confident must have been there for several days before death.

The Utility of X-Ray Work.—DR. ROBERT ABBE made some remarks on this subject, which he illustrated with numerous stereopticon views of *x*-ray pictures from his own work. The speaker said he was now using the *x*-rays frequently, both in his private and hospital work, and that he was much impressed with the utility of the rays as an aid to diagnosis in many obscure cases. Many surgeons still scoffed at the idea of employing this diagnostic aid, because in some cases it told us no more than we should be able to discover by our tactile sense coupled with surgical knowledge and experience, while, on the other hand, its use had thus far not been attended by much success in certain conditions regarding which we were often very much in the dark; such cases, for example, as the possible presence of a renal calculus, or a suspected fracture of the neck of the femur in old people, or in obscure cranial conditions. It was to be hoped, Dr. Abbe said that, success with the rays in those conditions would improve as time went on and the apparatus and technique of radiography were perfected. Dr. Abbe said that, while very excellent radiographs could be obtained with instruments of moderate penetrative power, the best work he had done was with the larger instruments, with more powerful penetration. Whether the static machine or the induction coil would give better results seemed to depend largely on the man who used the apparatus and his method of doing the work. The technique was such an important element that unless it was properly carried out even the best apparatus would prove disappointing in its results. Many excellent instruments were in the possession of physicians and surgeons, in whose hands they were impotent, because their successful use depended on the knowledge of the correct time exposure—for each part of the body, for each kind of plate used, for the working energy of the tube and machine at the time of use—all of which must be studied by the immediate development of the radiographic plate, in the house of the operator, by himself or by his office nurse or assistant. This implied a more or less intimate knowledge of photography, of mechanics constantly to readjust the machine and to obtain uniform power, and

at least an amateur acquaintance with electricity. The speaker said he had devised one expedient, which for more than a year had given him great satisfaction. In efforts to keep exact note of the case, time exposure, and history of each plate, he discovered that heavy lead-pencil writing on the paper enveloping the plate, made before exposure, would be indelibly reproduced on the plate within—inasmuch as the graphite was almost as opaque to the rays as metal. This saved all future confusion as to the subject matter on the plate, and did not affect the picture. He had often been asked as to burning the skin by the rays, and could only say that, after taking many hundred pictures with exposures frequently up to three-quarters of an hour, he had never seen the faintest effect on the skin of the patient. This he believed was due to never allowing the tube to be nearer the skin than twelve inches or, for long exposures, fifteen inches. With the best working of the tube and a twelve-inch coil of the Edison make, which he now used, he had gotten a good impression of renal calculus in a five-minutes exposure. To secure this, however, required careful and prolonged development of the plate.

Dr. Charles McBurney said that, while the possibilities of radiography had been at first regarded as almost unlimited, it was certainly true that up to the present time many of the *x*-ray pictures had been of a disappointing character. Moreover, a large number of conditions which had been beautifully illustrated by the *x*-rays could have been perfectly well made out by other methods of diagnosis. Among the most important uses that had been made of the rays thus far was the detection of foreign bodies and certain fractures. Dr. McBurney referred to one aspect of this subject which he said was frequently overlooked, namely, the value of *x*-ray pictures to patients who wished to set up the claim that they had not received proper treatment at the hands of the surgeon. Many of the radiographs of healed fractures, for example, showed apparently a considerable degree of deformity, and yet the functional results were perfectly good. This deformity, of course, was often more apparent than real.

Dr. Robert F. Weir said he agreed with Dr. McBurney that the *x*-rays had thus far not had a very wide application, their use having been practically limited to the detection of foreign bodies and an examination of the presence and outcome of certain fractures. From the latter experience the fact should be borne in mind that, excepting in very rare instances, a perfect reduction after a fracture was not accomplished. Aside from this, Dr. Weir said, thus far he had not been materially assisted in his surgical work by the use of the *x*-rays, and he still placed his main reliance upon other methods of diagnosis. In one case of foreign body in the œsophagus which he was able to feel with the bougie, a radiograph which had previously been taken showed the foreign body very indistinctly—so much so that he would have been unwilling to cut had he not been able to feel it.

Dr. Peabody said that thus far the use of the *x*-rays in cases of renal calculi had been quite unsatisfactory. In some cases of vesical calculi, however, the pictures had been very successful.

Dr. Weir thought this might be due to the depth and surroundings of the kidney.

Dr. F. P. Kinnicutt said that the *x*-rays had been used to a considerable extent at the Presbyterian Hospital, with rather unsatisfactory results, so far as diagnosis in medical cases was concerned.

Dr. W. Gilman Thompson said that in a case of aneurism of the aorta that had come under his observation the tumor could be made out very satisfactorily with the fluoroscope, while the radiographs did not reveal it at all. They simply showed a distorted chest.

Dr. V. P. Gibney said he thought Dr. Abbe had obtained exceptionally good results with the *x*-rays. Personally he had been rather disappointed with the use of the rays in early joint lesions, and he had come to the conclusion that in such cases palpation was of greater value than the radiograph. He had, however, found the rays very useful in the diagnosis of early sarcomatous tumors. The speaker expressed the belief that in the future this new diagnostic agent would have a much greater application than it had at present.

Dr. McBurney said he had recently operated on a young man of eighteen, who from his earliest infancy had suffered a great deal of pain which was always felt on the left side, below the last rib, just at the edge of the sacro-lumbalis muscle. The pain was boring in character. He had been under the care of a number of physicians, and had undergone various methods of treatment. He also had a slight lateral curvature of the spine, with the concavity of the curve toward the site of the pain, and for some time had worn a spinal brace. The examination of the urine was very suggestive of renal calculus, as it contained pus, blood, and albumin. Thereupon several radiographs were taken, which showed quite distinctly the presence of a stone in the left kidney. At operation, a large calculus was found in the anterior portion of the kidney, near the pelvis; this was removed, and the patient promptly recovered from all his symptoms. In connection with his report of this case, Dr. McBurney showed the radiographs and the calculus he had removed. The speaker said that, while the *x*-ray pictures in this instance were exceptionally good, he thought the diagnosis could have been made without their aid. The stone was of the uric-acid variety. In a number of instances pain and hæmaturia had suggested the existence of calculus in the kidney, and, although operation failed to demonstrate such condition, the symptoms had disappeared.

Dr. Peabody suggested that in those cases the relief might have been due to the fact that a small calculus was dislodged by the manipulation of the organ.

Dr. McBurney thought it more likely that the symptoms were the result of an interference with the circulation of the kidney, which was corrected by the manipulation. Slight malposition of the kidney, causing tension of the renals or ureters or kinking of the latter, might give rise to pain and hæmaturia.

Dr. Weir said the disappearance of the symptoms in some of these obscure cases when nothing definite had been found might perhaps be attributed to the fact that tension was relieved by cutting through the capsule of the organ. This theory had been advanced by Tiffany, and recently Harrison had resorted to this procedure in order to relieve the tension in cases of acute nephritis. There were other cases on record in which the pain was relieved by less drastic measures.

The Reason why Patients Recover from Tuberculosis of the Peritoneum.—It is apparent that when the abdominal cavity is opened and drained, saprophytes which enter through the drainage opening produce toxins which are fatal to or which inhibit the growth of certain tubercle bacilli. In some cases the bacilli are not killed by the toxins, but their growth is probably inhibited for a sufficient length of time, so that nuclein brought by the polynuclear leucocytes in the peritoneum can destroy them. This seems like a rational explanation of the fact that patients recover from tuberculosis of the peritoneum after operation; but on this theory the abdomen should not be closed immediately but should be drained in order to allow the saprophytes to enter through the drainage opening. —Robert T. Morris, "Lectures on Appendicitis and Notes on Other Subjects."

Clinical Department.

A UNIQUE CASE OF APPENDICITIS—OPERATION.[1]

By JOHN YOUNG BROWN, M.D.,

ST. LOUIS, MO.,

PRESIDENT OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

I REPORT the following case as clearly substantiating the assertion so frequently made by those surgeons who advocate early operation in all cases of appendicitis, namely, that we cannot be accurately guided, either by pulse or temperature, as to the nature and extent of the pathological conditions going on in and about the appendix in any given case.

I was requested by Dr. Paul Paquin to see in consultation with him Robert R——, aged forty-two years; occupation, fireman. Three days before I saw him he left work and came home suffering from what he termed a bilious attack. When seen by Dr. Paquin he was complaining of great nausea, intense abdominal pain, and great tenderness in the right iliac region. Pulse, 80; temperature, 99° F. Dr. Paquin prescribed for him, and as the patient grew no better he concluded that he had to deal with a case of appendicitis, and on the following morning I was called.

On examination I found the abdomen slightly tympanitic, with considerable tenderness over the seat of the appendix, but no mass could be made out. Rectal examination was exquisitely painful and considerable bogginess could be outlined on the right side. Pulse, 80; temperature, 98.8° F. I concurred in the diagnosis of appendicitis and advised immediate operation. The patient was accordingly moved to the Deaconess Hospital and prepared for operation. Assisted by Dr. Llewelyn Williamson, and in the presence of Drs. Paquin, Straus, and William Williamson, I opened the abdomen. From the date of the attack until the patient went on the operating-table his pulse had never been above 82, and his temperature never higher than 99.8° F. The nausea, however, persisted, and he had the general appearance of being a sick man.

The usual incision was made, and, the abdomen being opened, about a quart of stinking serum was found free in the pelvis. This was sponged out, and I found presenting in the wound a loop of ileum tightly bound down by a band-like adhesion. The presenting ileum was dark in color, and at first I thought would necessitate a resection. However, after the constriction was relieved, the circulation gradually returned. From the adhesions present about the cæcum it was conclusive that the patient had had frequent attacks of appendical trouble. The cæcum was tightly bound down by adhesions, and it was with some difficulty that the appendix was found. It was densely adherent to the cæcum, strictured, and gangrenous at the tip, with a perforation of about the size of a pea. After freeing the appendix, I cut it out to the head of the cæcum, and stitched up the opening with a double row of sutures. This was with difficulty done, owing to my inability to bring the cæcum up into the wound. The abdominal cavity was copiously irrigated with several gallons of hot salt solution and carefully sponged out; after several strips of gauze were placed in different directions for drainage the wound was closed. The patient reacted nicely, the gauze was removed in thirty-six hours, and his recovery was uneventful. In six weeks from the date of operation he was up and shortly after returned to work.

The above case, to me, presents many interesting points. Here was a man with a temperature and pulse almost normal, with every clinical symptom pointing to a mild attack of appendicitis, and yet when his abdomen was opened conditions were found which conclusively proved that had operative interference been delayed twenty-four hours he would have been beyond the reach of surgery to save. Several months ago I saw in consultation with Dr. H. H. Grant, of Louisville, a patient presenting symptoms almost identical with those seen in the case above reported. A diagnosis of appendicitis was made, and, the abdomen being opened, an intussusception was found, necessitating the resection of ten inches of gangrenous ileum.

I know there are those who contend that they can tell just which cases should be subjected to operation and just which should not; but the more I see of this condition the more I am convinced that we should operate in all cases at the earliest possible moment, and that the great danger in this disease is delay. On this point Fowler speaks very emphatically. "As soon as the diagnosis of progressive appendicitis is assured, the abdominal cavity should be opened and the appendix removed. If opium has been injudiciously administered and the progressive character of the case in hand is doubtful, it is better to err on the side of safety and remove the appendix at once. The conditions present are usually beyond the power of nature to remedy, while in the hands of a surgeon who pays strict attention to aseptic details, both preliminary to and in the course of the operation, the latter entails less risk to life than that which is involved in even a mild attack of appendicitis, which remains stationary at the end of twenty-four hours, with all its possibilities of lymphangitis, infection of the peritoneal cavity, retained muco-pus within the tube, and rupture of the latter into an unprotected peritoneal cavity."

Robert T. Morris, of New York, who has perhaps done more to develop the pathology of this disease than any other man in this country, in speaking of the indications for operation in appendicitis, says: "There are no groups of symptoms which will allow us to make a rational prognosis as to the eventual outcome, or the prospective complications, in any progressing case of appendicitis, and we must abandon the hope of having any such classification of symptoms for a guide in the future. Attempts will be made, from time to time, to classify symptoms for prognosis from small groups of cases, but they will fail because of the nature of the disease. I speak then unequivocally, knowing that some patients are to die and others are to suffer, unnecessarily, because their advisers will believe themselves to be upon a prognostic track. There is but one rule to be followed, and that is to isolate an infected appendix as promptly as we would isolate a case of diphtheria, and for practically the same reason, viz.: the infected appendix will probably infect other structures, and the infected throat is likely to infect other throats. An infected appendix is isolated when it is out of the patient. All cases of appendicitis that are otherwise within surgical limitations, and that are in reach of competent surgical services, are cases for prompt isolation of the appendix. Various periods of waiting have been tried, with the effect of proving that the question is wedge-shaped, with the greatest number of deaths at the broad waiting-end, and the smallest number of deaths at the point of isolating an infected appendix, while infection is limited to the confines of the appendix. We are held to our rule by two cardinal principles, viz.: (1) Every hour of progress of any acute attack of appendicitis means increased damage to viscera, and (2) with no infected appendix the patient would have no complications of appendicitis, if we leave him with no infected appendix."

Another point suggested by this case is as to the proper method of disposing of the stump in appendec-

[1] Read before the St. Louis Medical Society, March 12, 1898.

tomy. This question has been very much discussed of late, and many valuable papers have been written on this subject. For quite a number of years Price, of Philadelphia, has been practising a method which I believe to be ideal in the large majority of cases. The operation consists in cutting the appendix out of the head of the cæcum and closing the wound with a double row of sutures. The two methods now most in vogue—the method of Edebohls, which consists in the inversion of the entire appendix, and the method of Dawbarn, namely, the inversion and burying of the stump after amputating the distal two-thirds—with their various modifications possess many disadvantages. As pointed out by Fowler, it not infrequently happens that in gangrenous inflammation of the appendix the gangrene extends to the cæcal wall. Any method which leaves behind appendical tissue thus becomes the seat of inflammation, and is faulty in technique just in proportion to the amount of appendical tissue thus allowed to remain. He reports several interesting cases, in which after careful treatment of the stump by the inversion method there were subsequent extension of the gangrenous process, perforation, and death from general peritonitis. The excision method, as practised by Price and modified by Fowler, is ideal in its simplicity. After the surrounding parts were protected with gauze the cæcum is held between the thumb and index finger of the left hand; an assistant seizes the appendix with a forceps and the operator with curved scissors cuts the entire organ out of the head of the cæcum; the wound in the cæcum is then closed with a double row of sutures; the dirty sinus is removed, and we get a perfect coaptation of healthy tissues.

A CASE OF PARTIAL VAGINAL OCCLUSION IN A WOMAN PREGNANT EIGHT MONTHS.

By CARL F. GISSLER, M.D.,

BROOKLYN, N. Y.

On June 13, 1897, Mrs. M——, aged twenty-four, called at my office with her husband. A midwife sent these people, with the statement that, when Mrs. M——'s time was up she would not be able to deliver the baby, as there was no vagina for its passage. I made a brief examination, and found, half an inch from the introitus, a firm, elastic, and congested hymen, occluding all but a central orifice allowing an ordinary metal catheter to pass. Through this one-eighth-inch opening the sperm had entered and fructified an ovum in the uterus, the latter now being in about the eighth month of pregnancy, according to the woman's calculation. The child's heart could be heard through the abdomen. The urethral orifice was dilated widely, gaping over half an inch, and the lower part of the vulva was very widely separated and deeply congested. I told her to call again for operation at my office.

A number of physicians were invited, and on the evening of June 14, 1897, I rendered the vulva aseptic in the usual way, and with a hypodermic syringe injected a three-per-cent. cocaine-muriate solution in various districts of the field of operation. Crucial incisions were then made with the scalpel and scissors into the hymen, which was one-fourth inch in thickness near the central orifice and thicker near its insertions. The tissue was removed, and the raw bleeding edges were sutured with chromicized catgut to arrest the rather copious hemorrhage. Hot antiseptic solutions were used for irrigation, and the vagina was tightly packed with antiseptic gauze. Some whiskey was given her on account of the hemorrhage. She felt no pain during the operation. At her home next morning the gauze was removed, the parts were irrigated again with the solution, and more gauze was applied with a T-bandage.

Nothing was heard from her until July 1, 1897, when I was called in haste by the husband, who had been sent by the same midwife. Before going there I called upon a neighboring physician, requesting him to deliver the child, as I expected I could not sew up her lacerations so well if I had to do all the forceps traction alone or perhaps a version. The woman was chloroformed by me and the baby delivered by forceps by my medical friend. The baby weighed about nine pounds, and was alive and normal. The perineum was torn only about three-fourths inch, but the narrow vagina was torn some four inches. This rent I sewed up immediately with chromicized catgut, followed by hot antiseptic irrigations, the woman being under chloroform on a table.

The surroundings were of the poorest to be found in the city, dirty in the extreme; a neighboring woman occasionally visited her, and, as the husband could not provide for a proper nurse, septicæmia set in and death followed within less than a week. My advice to the husband on the second day to send her to a hospital, for proper nursing, was not heeded.

23 KOSSUTH PLACE.

AN EXTRAORDINARY CASE OF FOREIGN BODY IN THE LUNG.

By J. HENRY BARBAT, M.D.,

SAN FRANCISCO, CAL.

The following case came under my observation recently, and its history is deemed worthy of publication on account of the unusual and interesting features connected with it.

Fourteen years ago, the patient, then seven years old, was eating cherries and swallowing the stones; some amusing incident caused him to laugh, and during an inspiratory effort he suddenly aspirated a cherry stone into the trachea. This caused a violent fit of coughing, but the stone was not expelled; instead, it passed down deeper and lodged in one of the bronchi of the left lung. It did not cause him much distress until one day, a week after the accident, while sitting quietly, he was taken suddenly with a violent fit of coughing and expectorated a large quantity of muco-pus streaked with blood. The family physician was sent for and made a diagnosis of broncho-pneumonia, not giving credence to the story of the cherry stone. The patient's condition for the next two months remained about the same, as follows: Temperature, from normal to 100° F. in the morning, and from 100° to 104° F. in the afternoon. The pulse was rapid and there was considerable dyspnœa. Frequent coughing-spells occurred, with expectoration of muco-pus having a horrible odor. The patient was losing flesh rapidly and had profuse sweats. After two months the symptoms suddenly subsided and the patient convalesced rapidly. No further symptoms were noted until exactly a year later, when he had several hemorrhages from the lung. At precisely the same period every year for fourteen years these hemorrhages took place. The last ones occurred in the beginning of March, 1897. They were more profuse and occurred as often as four times in one day. His medical attendant advised him to have the lung radiographed, and, if the position of the foreign body could be determined, to have it removed by surgical means.

On March 17, 1897, Dr. Philip Mills Jones took a radiograph of the chest, exposing the patient for twenty minutes; one week later another exposure was made, lasting twenty-five minutes. After the first exposure the hemorrhages stopped, and the patient began to improve rapidly. Nine days after the last exposure

the patient noticed a slight itching on the chest in the region which was exposed to the *x*-ray tube. Two days later a violent dermatitis developed, which lasted six weeks and was accompanied by considerable pain and a good deal of secretion. Medication had but little effect on the dermatitis, which seemed to run its course in spite of all treatment.

The general improvement which followed the *x*-ray burn was little short of wonderful. Ever since the beginning of his trouble the patient had been unable to lie on his left side, as it occasioned coughing. This inability stopped immediately, and he was able to lie in any position without inconvenience. His chest, which was poorly developed, has expanded, and he is able to put his lungs to the most severe test.

On November 15, 1897, while lying in bed, he was seized with a sudden fit of coughing, and raised a solid mass of tissue about as large as a small hazelnut, which on close examination proved to contain the long-lost cherry stone. No further trouble has been experienced since then.

Whether or not the exposure to the *x*-ray or the burn produced thereby had anything to do with the expulsion of the cherry stone, it is impossible to say; but it is certain that some beneficial action was produced by the exposure, and more by the burn. This is further proved by the fact that Dr. Jones had another case of *x*-ray dermatitis at the same time, which also showed a most remarkable disappearance of hemorrhages, which had been persistent for a long while.

803 Sutter Street.

VICARIOUS MENSTRUATION FROM THE UMBILICUS.

By JAMES A. GARDNER, M.D.,

BUFFALO, N. Y.

We are told that vicarious menstruation is a periodical discharge of blood from some part of the body other than the interior of the uterus. It may come from almost any mucous membrane, from the nose, mouth, breast, or it may come from open wounds. I have not been able to find any record of hemorrhage from the umbilicus, so will give a short history of a case which has come under my observation.

Frances K——, aged sixteen years, Pole. First consulted me in February, 1898. Family and previous history negative. The patient complained of not menstruating, and came for relief. She had pain in the epigastrium and almost constant headache.

During June, July, and August, she had hemorrhage from the umbilicus, lasting from twenty to forty-eight hours each month. She became very much frightened, but because of the strange site of the bleeding was ashamed to consult a physician. Since then she had worn a tight band round the abdomen. During the autumn months she had no hemorrhage from the umbilicus, but had severe epistaxis and hæmoptysis. Since November she had had increasing tension of the abdomen and severe pain on pressure, not over the hypogastrium as would be expected, but over the epigastrium. She had had also chronic constipation and headache.

Physical examination shows some anæmia but not marked. Heart and lungs apparently normal. Abdomen very much distended, and painful on palpation. Umbilicus admits of a probe being passed about one and one-half inches. Vaginal examination gives patulous hymen; uterus and appendages are apparently normal, but hypersensitive.

This examination was not entirely satisfactory because of the impossibility of making a bimanual examination, the abdomen being so tense. A mild emmenagogue was prescribed and the patient began to menstruate in forty-eight hours, all symptoms being relieved. On a second vaginal examination, with abdomen lax, the uterus and appendages were found to be normal.

A UNIQUE CASE OF THE COCAINE HABIT.

By JOHN H. BILLINGS, M.D.,

NEW YORK.

I was called several days ago to see A. B——, who was suffering most intensely from abdominal pain, and who informed me that, having a stricture of the rectum, he was in the habit of using daily a large rectal bougie to dilate the contraction and obtain a satisfactory evacuation of the bowels. In the doing of this three hours previously, the instrument had slipped beyond reach, and in addition a small rubber syringe used to fill the rectum with cocaine solution had also gotten beyond control. He confessed to using cocaine habitually in this way, the passing of the dilator causing severe irritation at times. The patient in this plight called for prompt relief, as the temperature was elevated, pulse accelerated, and tympanites developing.

On examination, the syringe was found about two inches above the internal sphincter. No stricture presenting itself it was removed, and after exploring thoroughly the rectal cavity the finger came in contact with a cord. The patient being directed to bear down and make traction on the cord, the blunt end of the bougie was felt, and after considerable traction it came away, it being a large gum dilator, eighteen inches in length and one and one-half inches in diameter. The sphincter was greatly relaxed and presented no resistance to the passage of the foreign bodies.

This case is reported as an illustration of the peculiar method of taking cocaine and as a curious example of perverted sexual appetite.

AN ANTIDOTE TO THE RHUS POISON.

By A. T. HUDSON, M.D.,

STOCKTON, CAL.

In the Medical Record for April 16, 1898, is an article on Rhus toxicodendron, by Dr. Louis F. Frank, of Milwaukee, Wis. The author speaks of many remedies but gives no preference to any. This probably is no oversight, for I find such is the general tone of authors on the subject.

A few years ago my son put a Chinaman to clearing a piece of ground which was infested with a thick growth of poison oak, Rhus diversiloba, which had to be handled and burned. After one day's work the Chinaman reported sick, with hands and face swollen and painful. Remedies from the nearest doctor were obtained and applied. A carpenter who was working about the place was afflicted also. His eyes were closed and very painful. The medicine at hand was used on both patients for several days, with no relief. My son then sent to me, a hundred miles distant, for treatment. I ordered muriate of ammonium, one ounce, to be dissolved in two quarts of warm water. This solution was to be applied with cloth or absorbent cotton, covered with oil silk or rubber tissue. Relief followed quickly and in two days the sufferers were well or able to work.

Ten days later my son, after working a day with the shrub, found at night that his hands were swelling and inflamed. He applied the remedy at once, and by the next morning there was positive arrest of the malady. By frequent washing with the solution he and the others were not troubled thereafter.

Dermatitis venenata is usually self-limited, although

the limit may be twenty-four hours or as many days; hence the long list of uncertain remedies. Any medicine which will relieve pain and arrest morbid progress promptly is a remedy much needed.

The above cases and a history of many others might be cited to show that this drug, hydrochlorate of ammonium, is a pleasant and efficient curative and prophylactic.

DISPLACEMENT OF THE BLADDER CAUSED BY A RAILROAD ACCIDENT—CORRECTED BY LAPAROTOMY.[1]

By F. L. FORKER, M.D.,

BINGHAMTON, N. Y.

The case I report to-day is, as far as I am able to ascertain, unique, for a faithful inquiry and diligent search of medical literature have failed to elicit the fact that such a case has ever before been reported. That the bladder could be displaced upward to within one inch of the umbilicus and firmly held in that position for over one year does not seem credible, but the history I am about to give you will, I am quite sure, convince you that such has been the case.

November 15, 1897, I was called to see Mrs. G. P——, who gave the following history: The patient, aged thirty years, had enjoyed good health until October 10, 1896, when she was thrown from a carriage upon a railroad track, striking her back across the rail, and a woman weighing over two hundred pounds fell upon her, striking with her knees over the lower part of the patient's abdomen. This accident rendered her unconscious for two hours, after which she was placed in a carriage and driven fifteen miles to her home. Excessive flowing from the vagina took place during the journey homeward, but soon ceased after she was placed in bed. The next morning she noticed her abdomen to be nearly as large as a full-term pregnancy and very firm, and the slightest motion or jar would cause her severe pain. But after two weeks' rest in bed the pain and soreness diminished some and she assumed her household duties again. Painful urination and shooting pains through the pelvis, especially in the back, were the only symptoms complained of until March, 1897, when an excessive diarrhœa set in; the stools were very black and very fetid. Some days as many as twelve stools were passed, with a pint or more of thin, black, fetid discharge in each. In spite of cathartics and various other remedies prescribed to stop this diarrhœa, it continued for one month and then ceased of its own accord. Severe chills and fever followed, and the patient was again compelled to take to her bed. About the middle of April a second diarrhœa set in, but this one was described to be different from the first; the stools presented a light appearance, and the woman's physician assigned typhoid as the cause. Her condition then improved, and after a few weeks she was advised to go to the country. But she was no sooner there than her fever and chills returned and she was compelled to come home again. This condition continued from April to the date of my visit, November, 1897, at which time she complained principally of her bladder. She said that from the time her abdomen began to diminish in size, which was at the beginning of her diarrhœa in March, this difficulty in voiding urine had constantly increased, until it was so severe that she was compelled to resort to morphine for relief. At that time in order to void urine it was necessary to take a deep breath and bear down as she would in childbirth, and as soon as she stopped bearing down the urine would stop flowing. After she had expelled all the urine possible from her bladder, there would still remain a sensation of more being present, so she had a constant desire to urinate. She was also troubled with a dragging pain in the centre of the abdomen after voiding urine. This would vary according to the amount passed. When a large amount was passed it would be so severe that she would have to take an opiate for relief. As the abdominal walls were very thick and firm, examination was unsatisfactory, the only fact elicited thereby being that there were in the urethra no obstructions to the outflow of urine and that the pelvic contents were firmly fixed by a mass of adhesions. She was taking morphine steadily; her bowels were constipated, the urine was heavily loaded with mucus and phosphates, and she was in an extreme lithæmic condition. Consequently I ordered the morphine stopped, rest in bed, milk diet, lithia, saline cathartics, and hot applications over the abdomen for relief of the pain.

After this plan of treatment had been carried out faithfully for two weeks and my patient's discomfort instead of diminishing had continued to increase, I advised an operation as the only hope of relief. This advice being accepted, December 1, 1897, at the City Hospital, after the usual preliminaries and with the assistance of Drs. Farnham, Quackenbush, and Seymour, laparotomy was performed. The abdomen being opened, the bladder was found displaced upward, between the peritoneum and abdominal walls, to within one inch of the umbilicus, and firmly adherent to the abdominal parietes in front and to the peritoneum over the summit, sides, and posterior surface. The bladder was elongated and suspended in such a manner that it was impossible for it to empty itself, and, although the patient voided urine at the beginning of the anæsthesia, after the adhesions were separated over one pint was drawn off with the catheter. The pelvic organs were massed together by firm adhesions, some of which around the fundus of the uterus were separated, after which the operation was completed in the usual manner. The progress made by my patient after the operation was very satisfactory up to the middle of the fifth day, when, following a severe chill, her temperature rose in six hours from 99° to 103° F., pulse from 88 to 155, and trouble seemed to be at hand. But the administration of a laxative caused the passing of three fetid stools, after which the temperature and pulse gradually returned to normal and she made an uneventful recovery. During the first two weeks after the operation there was some burning sensation during the passage of urine; but that has now entirely disappeared and her bladder acts in a normal manner.

The history I have given describes the natural course taken by a large pelvic hæmatocele which has been evacuated by perforation into the rectum. The most interesting points in the case are the spontaneous evacuation of the large hæmatocele without causing death and the displaced position the bladder was left in. Perforation into the rectum may be followed by death from exhaustion or from infection caused by entrance of fæcal matter.

The only way I am able to explain this displacement of the bladder is that this large hæmatocele, by pressing upon the urethra, formed an obstruction to the outflow of urine; and as a result the bladder became overdistended, the summit rising up to the umbilicus, and, it being held in that position for some time, the accompanying peritonitis caused the adhesions which held the bladder suspended, when in March, five months later, the obstruction was removed by spontaneous evacuation of the hæmatocele. Operation in this case has been followed by the most happy results. In fact, it has saved my patient from the morphine habit, and changed her condition from one of intense suffering to one of comfort.

[1] Read before the Broome County Medical Society, January 4, 1898.

Therapeutic Hints.

Baths in Typhoid.—The good effects of the baths are: 1, the reduction of the fever; 2, the intellect becomes clearer, the stupor lessens, and the muscular twitchings disappear; 3, a general tonic action, particularly on the heart; 4, insomnia is lessened, the patient usually falling asleep for two or three hours after each bath; and 5, most important of all, the mortality is, under this plan of treatment, reduced to a minimum.—Osler.

Hemorrhage from the Bowel.—

R Liq. ferri sesquichlor	1.5
Aq. melissæ	150
Syr. cort. aurant	20

S. One to two teaspoonfuls every two hours.

—Bamberger.

Ichthyol in Conjunctivitis.—

R Ichthyol	50 gm.
Distilled water	50 "

Or a more dilute solution:

R Ichthyol	30 gm.
Distilled water	70 "

Apply to conjunctiva with a brush, and perform slight massage with the pulp of the little finger for a few moments.—*Pediatrics.*

Hydronephrosis.—

Cystitis and Urine Infection.—Dr. Max Melchior, in his book on "Cystitis and Urine Infection," reaches the following conclusions: 1. Every cystitis is due to microbes, with the exception of rare poisoning with chemical substances. 2. In general, we find in the urine of cystitis a pure culture of a single species, generally in very large amounts. 3. The bacillus which is found most frequently in cystitis is identical with a very common intestinal parasite, the bacterium coli commune; it is pyogenic and infectious, and of varying virulence. 4. In the urethra, the male prepuce, and the vagina, pathogenic bacteria are frequently found—bacteria which when conveyed into the urinary bladder can give rise to a cystitis. 5. The microbe itself does not give rise to cystitis; still there is a bacterium—proteus of Hauser—which by simply entering the urinary bladder may give rise to a cystitis. 6. The microbes can produce a cystitis only when the urinary bladder, on account of the influence of various predisposing circumstances, especially retention or trauma, is made susceptible to the infection. 7. Retention of urine, as well as trauma pure and simple, is incapable of producing a cystitis. The microbe is always the deciding cause. 8. The varying nature of the cystitis depends upon preexisting lesions and upon the character of the substrata in connection with the various peculiarities of the bacterium, among which the virulence must be rendered prominent. 9. In every cystitis the urine contains pus cells, but in very varying amount; the existence of a catarrhal cystitis is to be looked upon as doubtful. Even non-pyogenic microbes may cause a suppuration of the urinary bladder. 10. The ammonuria may be a necessary condition for the occurrence of a cystitis; most frequently, however, it is but a subordinate phenomenon which appears in the course of cystitis or remains away altogether. The majority of cystitis-cases are acid. 11. Besides tubercle bacilli, an acid cystitis may depend upon the bacterium coli commune, the streptococcus pyogenes, and on rare micro-organisms (gonococcus of Neisser, bacillus typhi abdominalis). If the sterile urine does not produce any culture upon the ordinary media, the great probability is that a tuberculous cystitis exists. 12. There exists a real gonorrhœal cystitis, caused by the gonococcus of Neisser. 13. The urinary fever is partly due to transmission of the urinary microbes into the blood, partly—and certainly more frequently—to an absorption of the soluble toxins which occur in the urine. 14. To prevent a cystitis, we must not only be certain of a thorough asepsis of the urethral orifice, but we must also irrigate the urethra with boric-acid solution. 15. In the local treatment of cystitis nitrate of silver is the sovereign remedy.

Excessive Treatment in Disorders of Infants.—Professor Neumann, of Berlin, gives the following warnings: 1. Do not bathe the infant and thus remove the vernix caseosa, which is itself aseptic. The first bath should be given after the navel wound has healed. 2. Avoid too much cleansing of the mouth of the infant by rubbing and scrubbing it out. 3. Refrain from scarifying the gums with the idea that dentition is a pathologic process.—*Medical Council.*

Vomiting Following in the Course of Intestinal Affections.—

℞ Menthol..... 0.50 cgm.
Cognac..... 40 gm.
Tincture of opium..... 10 gm.
M. S. Take twenty drops several times daily.

—Peck.

The Maximum Dose for Children of Various Drugs in the Form of Suppositories.—It is often the case in children that the digestive tract is so irritable that all medication is rejected, while the stronger drugs frequently call forth vomiting and diarrhœa, and thus fail to produce the desired effect. Force is sometimes required for children who refuse to take medicine, and the resulting excitation is harmful; on the other hand, suppositories may be introduced into the rectum unknown to the child. The absorption per rectum is complete, but is altered by various conditions; the process is slower than stomach or intestinal absorption. We can therefore always begin with the same dose as is prescribed per os, and this dose may be increased after the tolerance of the child is ascertained. The drug should be thoroughly incorporated in the suppository to insure gradual absorption. *Der Kinder-Arzt*, 1897, gives the maximum dose of the following drugs in suppository form: Opium: of this powder, 1 mgm. for each year of the child's age; this dose may be repeated in severe cases every two hours; watch carefully for toxic symptoms (narcosis, myosis). Aconite must be employed in large doses in children to produce its effects; to test the susceptibility, give 1–2 drops of the tincture up to 10–12 drops in twenty-four hours for each year of age. Belladonna: for each two years of age 1 cgm. of the extract may be used in twenty-four hours, this quantity to be divided into four suppositories. Digitalis: as the powder is very slow of absorption, the tincture should be employed in maximum dose of 4 drops for each two years, divided into two suppositories. Caffeine may be combined with equal parts of benzoate of sodium, and given in two suppositories of 1 cgm. for each year of age. Quinine is best given in suppository form, the daily dose not to exceed 15–20 cgm. for each year of age; it should be divided in two parts. Antipyrin same dose as of quinine. Salicylic acid, 50 cgm. for each year, in three or four doses. Nux vomica, 1 cgm. for every two years, in three suppositories; children over ten years of age should first receive strychnine. Mercury must be employed in exceptional cases only, and then only in the form of calomel, of which use 5 cgm. in one suppository for each year. Iodine and the iodides are splendidly borne by the rectum, and absorption is complete; 20 cgm. for each year, in two parts, is the maximum dose; 5 cgm. when administered for a long period. Bromides, same dose as of the iodides, except in cases of severe spasm, as in stridulous laryngismus, when 1 gm. for each year should be given in two doses following closely upon one another.

Bronchitis.—

—Lyon.

Treatment of Catarrh of the Eustachian Tube and Middle Ear.—Dr. Tschouprina (*Revue de Thérapeutique*, January 1, 1898) reports two rebellious cases of catarrh of the middle ear, in which considerable relief was obtained by intratympanic injections of bicarbonate of sodium and chloride of sodium. The author adds that this treatment gives good results after insufflation has failed. He employs a lukewarm solution of a mixture of equal parts of these ingredients, injecting every day from fifty centigrams to one gram of the solution. He uses a Pravaz syringe fitted with an ordinary auricular catheter introduced into the Eustachian tube.

Alcoholic Anuria Treated by Artificial Serum.—Dr. Dumont (*Le Scalpel*, January 2, 1898) reports the case of an alcoholic individual who was suddenly seized with suppression of urine. This patient was very stout and it was difficult to outline the bladder by palpation and percussion. At the time that the author first saw the patient he had not urinated for twenty-four hours. He had taken great quantities of diet drinks of the diuretic class; his temperature was normal and his pulse very rapid. He passed, at long intervals, a few drops of albuminous urine. The following day his condition remained the same. A sound introduced into the bladder removed only a few drops of urine. The following day his general state became bad; pulse, 140. The evening of the second day the anuria persisted, in spite of large doses of theobromine. The situation became grave, and Dr. Dumont, basing his act on knowing the good effects of artificial serum in cases of uræmic eclampsia, prepared a sterilized solution of salt water. A litre was injected at three different places—the pectoral, abdominal, and axillary regions—at the same time. On the following day the patient was completely transformed. A half-hour after the injection he had a sudden evacuation of gas and he commenced to urinate. At the end of the first day the quantity had reached three litres and the albumin had disappeared.

Rheumatism.—

℞ Sodium salicylate..... gr. xc.–cxx.
Syr. of bitter orange peel..... ʒij.

OUR LONDON LETTER.

(From our Special Correspondent.)

TREATMENT OF CHRONIC BRIGHT'S DISEASE—ROYAL ARMY MEDICAL CORPS—CONVICTION OF COLLINS—LUNACY LAW—"PHOSSY JAW"—UNIVERSITY FOR BIRMINGHAM—BEQUESTS TO CHARITIES—DEATHS.

London, July 8, 1898.

The treatment of chronic Bright's disease was discussed last week at a meeting of the Medico-Chirurgical Society, apropos of a paper by Dr. Ewart, who found the usual methods of dealing with tubal nephritis unsatisfactory, as they do not cure the disease and often fail to relieve the symptoms. On the other hand, the spontaneous recovery of some cases after long periods of ineffectual treatment indicates that the lesions are not necessarily fatally destructive of the renal structure. The cases on which Dr. Ewart founded a proposal for a departure from the usual treatment were of strictly uncomplicated tubal nephritis, which leaves no permanent lesion behind and may be regarded as an inveterate epithelial catarrh. In other varieties this catarrh is only one of the features, and in them the prognosis and treatment are less hopeful.

The features of tubal nephritis are dropsy, anæmia, oliguria, and cachexia, the last disguised by persistent œdema and paving the way to complications or exhaustion. The treatment proposed by Dr. Ewart is directed against the dropsy, which, although it is nature's protection against fatal intoxication, is also a danger; for the œdema oppresses the tissues, chokes the lymphatics, and impedes metabolism—thus hindering nutrition, both local and general. The impeded nutrition of the kidney is aggravated by the absence of a free lymphatic flow, and thus the tubal nephritis becomes a lymphatic disease, and treatment should be directed accordingly. Dr. Ewart's plan is to unblock the lymphatics, to establish a flow into them from the blood so as to remove solid and toxic products, and to quicken artificially the lymphatic circulation. When œdema is general or localized elsewhere, he would bring it to the feet by slanting the bed and giving it exit by Southey's tubes or even by small incisions when they could be made into dilated lymphatics—preferably at the back of the ankle. Antiseptic measures must precede the operation and be kept up by dressings. The skin of the whole foot should be covered with vaseline to prevent soakage. In one case drainage had been kept up for two months. A liberal diet can be adopted during the drainage, though sometimes it may be advisable to return to milk diet for a few days, which tends to promote the flow if there is a tendency for it to dry up. One object of this plan is to restore cardiac energy and nutrition, after which drug treatment might afford better results. Though this plan was devised for dropsy, it may be useful in other cases. In uræmia without dropsy it might supplant venesection. In one case not admitting severe measures Dr. Ewart established an artificial œdema by pressure with the tourniquet and a Martin bandage, and kept up a flow from a single incision for seven days.

Dr. H. Dickenson, without denying the part of the lymphatics, held that the tubes were the most important channels of excretion, as shown by the casts and epithelial débris, often so abundant as to form a deposit visible to the naked eye. Drainage was an old practice, discredited by causing erysipelas or septic cellulitis, but now attended with very little risk under strict Listerian precautions. He thought the relief to the uræmic process must be very slight and that there was some tendency to recovery in all cases, and that

this usually manifested itself contemporaneously with hypertrophy of the left ventricle.

Dr. Norman Moore said it was rare to examine post mortem cases of renal disease, except acute ones, without finding degenerative processes in the heart wall. There was a great difference in the two sexes. Dr. Moore estimated a woman's expectation of life in this disease as three times that of a man, which he attributed to the different ways of life, and suggested that a convalescent man should not attempt active exercise but adopt a mode of life like that of women engaged in domestic duties.

Sir Dyce Duckworth took a less gloomy view of prognosis than Dr. Ewart, and relied on warmth, diuretics, and tonics without restricting his patient to milk diet; but free incisions often gave great relief. The prognosis was worst in strumous persons.

Dr. Ewart in reply insisted that the removal of the dropsy was only a preliminary to feeding up the patient and improving the general condition, which could not be done while all the cells of his body were sodden from the œdema. He could not see how ventricular hypertrophy being associated with fibrosis of the kidney would leave the patient better off. In fact, that hypertrophy seemed to him a very undesirable accompaniment.

The Queen having approved the new warrant constituting the royal army medical corps, it is published in the army orders for this month.

The fashionable abortionist Collins has at length met his doom—seven years' penal servitude. He has had some narrow escapes before and was once convicted of forgery, but in some mysterious manner was not punished. The case is notorious, and no doubt you have heard of it. He had been struck off the "Register" but carried on practice up to now with impunity. He had occupied a good position, held good diplomas, and might, one would suppose, have done well had he not fallen into illegal ways. The trial raised important medico-legal questions.

The lunacy laws are strict and medical men should be well aware of the danger of infringing them. Yet every now and then there is a prosecution against a doctor for receiving into his house a lunatic without the necessary certificates; one has just been committed for trial on this charge, and he seems to have only himself to thank for this consequence of evading the law.

Infringement of the wholesome hygienic laws we have deserve sharp penalties. Since the conviction of the match-making firm for concealing cases of "phossy jaw," attention has been directed to plumbism as equally important. There are other cases, too, which deserve the attention of the public and the legislature. In regard to the phosphorus case, the money penalty inflicted on the company would be a mere trifle out of its pockets, and it may be questioned whether more severe punishment should not be inflicted in such cases. I am sorry to notice that the medical officer of the company omitted to report the cases. The omission cannot be defended, and I hope no other practitioner will thus act as a shield to firms engaged in dangerous trades. The profession has a clean record in such matters, and it is most vexatious to have it broken.

Birmingham desires to have a fully equipped university for the Midlands. With Mr. Chamberlain as one of her representatives and so important a member of the cabinet, she should have no difficulty in obtaining a charter or an act, if her rich manufacturers hasten to provide funds adequate for the purpose.

Under the late Sir Robert Rawlinson's will, St. Thomas' Hospital will benefit to the extent of about £35,000. The late Mr. E. O. Bleackley left £500 to Owens College for a scholarship to be named after him, £500 to the Brighton Hospital, and £100 each to the Children's and the Lying-in hospitals and the dispensary at Brighton. The late Colonel Sylvester l'Amy bequeathed £5,000 to the Edinburgh Infirmary and a reversionary interest in a larger sum. The residue of his estate is to be shared by Guy's, St. Thomas', Charing Cross, the Consumption, Cancer, Queen Charlotte's, and some other hospitals. Altogether the amount he has left for charities will probably reach about £20,000. The late Miss Day, of Oxford, bequeathed £5,500 to Oxford and Portsmouth hospitals.

Henry Case, M.R.C.S., etc., lately medical superintendent of the Leavesden Asylum, died on the 28th ult., aged fifty-five years. Among other recent deaths are those of three surgeons-general—W. H. Adley, aged seventy years, F. M. Clifford, and J. C. Morice, aged sixty-one years, all of the Indian medical service; also those of Surgeon-Lieut.-Col. B. W. Fowler, A.M.S., Brigade-Surgeon-Lieut.-Col. W. A. Barren, I.M.S.

"APOMORPHINE AND ITS USES."

To the Editor of the Medical Record.

Sir: The issue of the Medical Record of July 2d contains a very interesting article from Dr. Visanska, on "Apomorphine and its Uses." He gives apomorphine quite an extended range of therapeutic value, but fails to mention the condition in which, in my practice, it has given the most valuable results.

I refer to hysteria. Apomorphine here is the remedy *par excellence*. It may almost be classed as a specific in the acute hysterical conditions. There are few clinical pictures which present such wonderful and sudden contrasts as that of a patient with teeth clenched, muscles rigid, with opisthotonos, or throwing herself and her anxious attendants about, transformed in three or four minutes by one-tenth grain of apomorphine hypodermically into a docile, relaxed, limp, and vomiting individual, her pride and alleged pains gone together, and a restful sleep in store for her after the emesis is over. I have never seen any unpleasant complication resulting from the use of this remedy, though I have depended almost solely on it for six years and have used it in several cases in which pregnancy coexisted. Instead of a hypodermic, a dose of from one-tenth to one-fifth grain may be given by the mouth, and a satisfactory though less prompt result will be obtained. I regard apomorphine as by far the most prompt, reliable, and, both to the patient and to the physician, satisfactory drug in the treatment of this condition, of which I have any knowledge.

F. J. Campbell, Ph.M., M.D.

Fargo, N. Dak.

To the Editor of the Medical Record.

Sir: Two noteworthy papers have recently appeared on the therapeutic value of apomorphine—one by Dr. Robert H. Babcock (*Medico-Surgical Bulletin*, June 10th), the other by Dr. Samuel S. Visanska (Medical Record, July 2d). Both writers, after ample experiment and trial, agree to the superior merit of this drug in conditions and circumstances under which innumerable other drugs are less advantageously employed. Their emphatic recommendation to widen the application of this effective remedy under appropriate circumstances could be taken as an expression of sincerity based on unbiassed conviction. Aside from the emetic quality of apomorphine, which surpasses every other known emetic in rapidity of action and absence of gastric disturbance, its sphere of usefulness is pre-eminent in diseases of the respiratory organs, acute or chronic. No one who has observed the

action of the alkaloid in those diseases can fail to indorse the claims set forth by the two writers. Given in small doses by mouth, it neither nauseates nor depresses. In infants and children, among whom my experience with this remedy is largest, apomorphine not only produces the desired expectorant effect, but distinctly calms excitement, allays restlessness, and encourages quiet, refreshing sleep. I have seen these effects so often that I have learned to anticipate and count on them. No other drug of that class is possessed of such valuable properties.

The object of this letter is not only to emphasize that which was so well and convincingly put forth by the above-mentioned authors, but to direct attention to an additional and much-neglected use of apomorphine. I refer to its great value in whooping-cough. It does not remove the cause, nor does it shorten the duration of the disease—none of the vaunted remedies does; but it palliates most of the distressing symptoms, such as the frequency and severity of the paroxysms; it induces better rest at night, and, paradoxical as it may seem, it overcomes in some instances the tendency and inclination to vomit. The two remedies which are conspicuous to-day in the treatment of whooping-cough are belladonna and quinine; but the belladonna, in order that it may do good, must be pushed to the point of tolerance, which is practically equivalent to the degree of poisoning; and quinine is possessed of that horribly bitter taste which is objected to by adults and dreaded by the young, to say nothing of cinchonism and gastric irritation which will surely result from its long use.

Apomorphine is free from all these bad features. There is no need of watching the child's pupils; no need of calling in all the neighbors to hold the struggling victim while the bitter potion is poured in its mouth or while the suppository is forced into the rectum. Apomorphine avoids all that.

A good working formula is that which is employed by Dr. James T. Whittaker (Hare's "System of Practical Therapeutics," vol. ii., p. 546) in his treatment of acute bronchitis:

℞ Apomorphinæ hydrochloratis..... gr. ss.–i.
Acidi hydrochlorici diluti..... gtt. x.
Syrupi..... ʒss.
Aquæ menthæ piperitæ..... ʒiss.
M. S. A half to one teaspoonful every two hours.

Next to sunshine and air, apomorphine with me is the staple remedy in whooping-cough, and, until the universal panacea arrives, I recommend it to my brethren as the very best on the long list of remedies for that dreaded disease of childhood—pertussis.

R. Abrahams, M.D.

156 Clinton Street.

NEEDLESS NOISES.

To the Editor of the Medical Record.

Sir: In regard to your timely editorials about street noises, the pertinent question suggests itself: Has not the Board of Health the power to suppress them? The distinct province of this board is to have supervision over the health of the community, and surely the various nuisances you complain of inflict as much damage on the individual—whether sick or well—as many of the diseases which the board of health pronounces contagious. A little more zeal in the direction indicated and less in the line of selling antitoxins would be acceptable to the community.

Egbert H. Grandin, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 23, 1898:

	Cases.	Deaths.
Tuberculosis	167	145
Typhoid fever	18	4
Scarlet fever	87	8
Measles	130	8
Diphtheria	150	19
Laryngeal diphtheria (croup)	7	3
Cerebro-spinal meningitis	0	9

Deaths of Old People.—The obituary list of the London *Times* for June 18th was a somewhat remarkable one. Two children eliminated therefrom, there are thirteen deaths recorded, with an aggregate of ten hundred and five years, or an average of over seventy-seven years; five out of the thirteen reaching eighty-two years.

Out-door and In-door Life.—The admitted advantage of an out-door life in many morbid conditions, and notably in consumption, seems to point to the conclusion that there is something definitely injurious in the in-door life which is now the common existence among civilized people. It is a striking and a startling thing that the mere removal of a patient into the open air should lower his fever, should remove his night sweats, and take away his hectic, and it is difficult to avoid the conclusion that, if these symptoms are removed by the purity of the air outside, they must have been largely caused by the impurity of the air within the house. Nor have we any right to assume that it is the consumptive only who suffers. Doubtless the healthy struggle against and overcome evil influences before which those who are tuberculous succumb, but that is not to say that in the struggle we do not suffer; and, indeed, the facts recently brought forward are sufficient to show that the stuffy life of warmth and comfort which civilized man now "enjoys" is bad for the health, even of the healthiest. We make our windows fit, we pad our doors, we shiver at a draught, we surround ourselves with woollen curtains, dusty carpets, and fluffy, luxurious upholstery. We breathe the same air over and over again, and then we wonder that we are not strong and vigorous. The fact is, we are daily using up the exuberant vitality with which nature has provided us in struggling against artificial conditions. How powerful for evil, how deteriorating these conditions are, are shown by the fact that their mere removal gives back to the consumptive that vitality which enables him to overcome the seeds of disease within him. Fresh air is not a thing to be taken in little doses once a day, but a thing to live on.—*The Hospital.*

Orrhotherapy of Anthrax.—Dr. Sclavo reports the results of seven cases of malignant pustule treated by him with injections of antianthracic serum, previously used with effect on animals. All seven of the patients made a good recovery, but since the disease is not necessarily fatal he considers that more ample statistics are requisite for a final judgment. He points out that in the case of animals the serum is far more active and efficacious when injected into a vein than subcutaneously.

Paper Teeth.—Dentists in Germany are using false teeth made of paper instead of porcelain or mineral composition. These paper teeth are said to be very satisfactory, as they do not break or chip, are not sen-

sitive to heat or cold, and are not susceptible to the moisture of the mouth, and from their peculiar composition are very cheap.

Consumption of Air.—It is computed that when at rest we consume 500 cubic inches of air a minute. If we walk at the rate of one mile an hour we use 800; two miles, 1,000; three miles, 1,600; four miles, 2,300. If we start out and run six miles an hour we consume 3,000 cubic inches of air during every minute of the time.

A Banana Diet in Typhoid Fever.—After a long experience with typhoid patients Dr. Ussery, of St. Louis, regards the banana as the best food for them. The banana is almost wholly absorbed by the stomach, easily digested, and very strengthening.

The Aseptic Influence of Cold.—An English journal says that it is highly probable that microbes do not exist in polar regions and at great elevations. Most probably all of them are killed by intense cold. It is for this reason that frozen meat can be preserved fresh for an indefinite time. The fossil mammoths which have been discovered in the banks of Siberian rivers, embedded in ice, are often quite undecomposed, and their flesh is eaten by dogs. Professor Tyndall experimented on the vitality of microbes by exposing solutions of sugar to the air on the higher summits of the Alps, where he found that fermentation did not take place, whereas at lower levels, where the temperature was higher, the liquids quickly became turbid, owing to the presence of microbes. Dr. Nansen furnishes a confirmation of the truth of the above statements. He informed the writer that as soon as his companions returned to Norway after their sojourn in the extreme north they all caught cold, but had been entirely free from this ailment during their prolonged absence. The inference is that reproduction of the catarrh microbe had been prevented in the severe cold of the polar region. That cold, while repressing activity, does not always kill pathogenic micro-organisms we know, since virulent typhoid bacilli have repeatedly been found in ice.

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending July 23, 1898:

SMALL-POX—UNITED STATES.

Rats as a Hair Tonic.—A Chinese gentleman advocates the use of the rat as an article of diet, and makes the following remarks on its properties as a hair restorer: "What the carrot is to a horse's coat a rat is to the human hair. Neither fact can be explained, but every horseman knows that a regimen of carrots will make his stud as smooth and lustrous as velvet, and the Chinese, especially the women, know that rats used as food stop the falling out of hair and make the locks soft, silky, and beautiful. I have seen it tried many times, and every time it succeeded."

YELLOW FEVER OF THE TROPICS.

By WOLFRED NELSON, C.M., M.D., F.R.G.S.,
NEW YORK.

In the following article, embracing an experience of eight years in the tropics, I shall deal with yellow fever as I knew it at Colon and Panama on the Isthmus of Panama, at Mazatlan on the west coast of Mexico, and at Havana and Santiago de Cuba. No attempt will be made to enter into any minute classification of the disease. Some writers have divided it and subdivided it, to the great and lasting perplexity of many to whom the disease is a new one.

In its every-day conditions in the centres named, it will be found as mild, severe, and malignant yellow fever.

In what follows I have in mind, as a general statement, the new comers within the tropics—men, as a class, from temperate and northern climates, a class particularly susceptible to yellow fever.

Mild Yellow Fever.—The cases under this heading present the following characteristics: Flushed face, well-marked frontal headache, some pain in small of back, general malaise, restlessness, a history of constipation. Man a new comer. Pulse slow and hard, 70; temperature, 101°–102° F. Tongue furred. Urine high colored. In these the history of a chill may not be had. Nausea and vomiting in some cases. Many of them have become ill quite suddenly; previously quite well. On the second day a trace of albumin may be found in the urine. The following day it will have increased. In addition to the usual symptoms, albumin must be present or the case is not one of mild tropical yellow fever.

French writers term the above *fièvre d'acclimation*, or a fever of acclimation. Such it is, and the acclimation means a tissue change.

The mild yellow fever is a disease of a single paroxysm or access. Such attacks mean subsequent immunity from yellow fever.

Severe Yellow Fever.—In this class the clinical picture may be the same for the first day. Later the headache is more severe, frontal or occipito-frontal. Pulse full, hard, and slow for a fever, 70 to 80. Pain in the back, generally lumbar, often of an agonizing kind. Tongue furred; tip and edges often red at outset. The usual history of constipation, often extending from three to four or five days. Man a new comer. The red flush of the face is more marked. It is the well-marked boiled-lobster hue. Later the color extends to trunk and limbs. At outset the eyes may not furnish any information. The conjunctivæ may be quite clear. Later they become suffused, vessels congested. In them the yellow color first becomes discernible. That color of skin and conjunctivæ gives the disease its name. The heat of the skin is very peculiar; the hand when placed on the body tingles as if a gentle current of electricity were playing over its surface. This burning or biting heat has no counterpart in malarial fevers. In this class the history of a well-marked chill may be had, but not always. The duration and severity of the chill have a significance all their own to the physician. Persistent and severe chills, often half a day to a day in duration, mean troublesome and often fatal cases. In some patients the invasion may be very sudden, as by nausea or faintness, with no chill. Many of these are cases in which the nervous symptoms are marked throughout the case. High temperature, delirium, etc.

Symptoms of gastric disturbance set in early. Patient complains of his stomach, often of a burning sensation. Even at invasion, pressure over the pit of the stomach causes pain. The gastric symptoms increase. On the second or third day the vomiting becomes marked—first, a white fluid, called by Dr. Blair, of British Guiana, "white vomit." Any pressure over the stomach now causes intense pain. Urine first day or two high colored and excreted in fair quantity. Frequently on the second day a trace of albumin may be found in it. It must be present if the case is one of yellow fever. It is pathognomonic. Its appearance, *quoad* the symptoms given, constitutes a severe case of tropical yellow fever.

Temperature: In this form it runs up and keeps high—102°, 103°, 104° F. on the second or third day; this while the pulse is slow and hard. The vomiting is almost constant and most distressing; the stomach rejects everything. Constant restlessness. Pain in back often excruciating and indescribable.

The changes in the blood are rapid. Its disintegration has commenced. To detect the yellow color early—that of the skin—pressure is made by placing the hand on the chest; when suddenly withdrawn, the impress of palm and fingers is sharply mapped out in light canary yellow, while the surrounding skin is of its scarlet hue. This is another indication that the case is a severe one.

With the persistent elevation of temperature the general condition of the patient becomes worse. The injection of the conjunctivæ increases. Sordes form on teeth. The breath becomes fetid. Sore throat frequently is complained of, due to stripping of the mucous membrane of throat and mouth. Blood exudes and collects on teeth and lips. The odor of the breath becomes unbearable. This stripping of the mucous surface and exudation of blood are a symptom of bad omen.

The urine becomes scanty; the albumin increases steadily. In many cases the percentage got by boiling is very high. The percentage has a direct bearing on the case—as the life currents are destroyed the quantity of albumin increases. Such are the general symptoms in severe cases. It must be remembered that the symptoms do not appear in any fixed order. No arbitrary law can be made for such cases.

In cases in which the first or initial fever is merged into the "period of calm," the disease runs a course of three stages. The "period of calm," as it is termed, is reached on the fourth or fifth day. It is a mere remission. Temperature may fall two or three degrees. Pulse becomes softer. The patient is better, as far as a layman is concerned—the "period of calm," alas! is most deceptive. It may last twenty or thirty or more hours—when the "secondary fever" comes on. Soon,

in a few hours, it has reached the maximum temperature of the initial fever. Vomiting is renewed. There may be suppression of urine; if any urine may be had for testing, it is laden with albumin. Pulse, 70 to 80; respiration, 30 to 40. Hiccough. Vomiting again sets in, with all of its old violence. In some cases the patients seem dull and wholly indifferent; in other cases the nervous symptoms are marked, and delirium may cause much trouble. The patient frequently requires two or three attendants to keep him in his bed.

The majority die, but when one escapes the change frequently is initiated by a profound sweating. Later it is followed by some sleep. Temperature falls; pulse loses its wiry hardness; the hitherto inactive kidneys renew their function; a little highly albuminous urine is passed; the fever ceases. Convalescence is slow and very tedious.

Malignant Yellow Fever.—In the malignant cases patients die during the initial fever. While the symptoms in the severe form are grave, in the malignant cases they are intensified from the start. The patient is struck down by the intensity of the blood poison. Generally at the close of the second or third day the malignant nature of the case is quite clear to his medical attendant. Nothing checks the vomiting or eases pain—the temperature reaching 106° and 107° F. The latter was the maximum noted by me. Such patients die; the classic exception is lacking. Even when wholly unconscious, any pressure over the stomach—particularly if made just below the xiphoid appendix—will make the patient writhe.

In some of the severe and in all of the malignant cases the yellow tinge of the skin becomes marked before death closes the scene.

Black vomit and black-vomit stools are met in nearly all the fatal cases. A man may have a little black vomit and recover.

The blood has been destroyed. Dr. Girerd, formerly surgeon to the Panama Canal Company, devoted much time to a study of the blood in these cases. It was a mere fluid, having no red corpuscles—a fluid full of débris of corpuscles. Knowing and recognizing the necræmia or death of the blood, many phases of the clinical picture become clear to us.

Such, very briefly told, are the every-day cases of yellow fever in the tropics—mild, severe, and malignant.

At times a physician may have doubts as to the exact nature of the case that confronts him. Is it malaria in a new comer or is it yellow fever? Much invaluable time may be saved by making quinine and sulphate of sodium combined the diagnostic agent. My plan was simple—instant action to clear up the doubt. I gave fifteen grains of quinine with two drachms of sulphate of sodium every three hours until two or three doses had been given. If malaria, the joint action of quinine and sulphate of sodium cleared up the doubt; if not, then I knew that I had to deal with yellow fever.

The treatment of yellow fever as laid down in the text-books leaves much to be desired. There are so many remedies and suggestions that the whole constitutes a general confession that we are lamentably in the dark regarding this yellow foe of the tropics.

After a time I simply abandoned the text-books, as far as treatment was concerned. Consultations were in order, but the patients died. The consultations seemed to be for the safety of the attending physician.

When called to see a patient—a new arrival who had the symptoms described under the head of mild yellow fever—with a view of saving time I gave the quinine and sulphate of sodium. That combination of quinine, dilute sulphuric acid, sulphate of sodium, and water was a mixture of mine born of tropical experience. Recall the history of constipation. Few if any of the cases so treated proved to be malaria, but time in such cases frequently means a life and the doubt had been removed.

My method was a very simple one—one that can be used anywhere. The quinine mixture was given as stated. Next the patient was prepared for a vapor bath. The man was stripped and seated on a chair with a wooden seat. His feet were placed in a bucket of hot water, as hot as it could be borne without burning. A pint of hot lemonade was given him, or as much of it as he could drink. He was covered with blankets. A spirit lamp was lit and placed under the chair, of course under the blankets. They were used for confining the heat and moisture. Soon, very soon, perspiration would show itself; next to roll down face, arms, and body. In a few minutes the hot dry skin lost its angry scarlet hue, the pulse became softer, the headache less. General improvement followed—to the great relief of the patient and his friends. The vapor baths lasted ten or fifteen minutes. They never were pushed to faintness. The man was lifted *en masse* and put to bed and covered with blankets. Frequently he kept on perspiring freely for one or two hours.

If the skin again became dry and the pulse hard, the vapor bath was repeated once or twice if necessary. If the salts acted promptly, the general betterment was increased.

Next in order I gave him freely to drink of an acid mixture—any of the mineral acids largely diluted. It was a grateful mixture. By this very simple treatment two great and to me most important indications had been met—the loaded intestines had been emptied, the hot and burning skin had been forced to act and eliminate its secretions. In the majority of the cases the men had been eating heartily up to the time of sending for me, with constipation extending over several days.

By this treatment the patient had been placed in the best condition to fight the disease. Time, the essential thing in such cases, had been saved.

Mustard over the stomach to check the obstinate vomiting, small pieces of ice, water, and the acidulated water. In the severe and malignant cases patients had no desire for food or broth. Morphine was contraindicated by the condition of the kidneys. The symptoms had to be treated one by one.

In my experience a temperature of 105° F. and upward in many cases meant delirium, sometimes violent. In 1880 I introduced the ice pack in such cases—cloths placed on blocks of ice and applied to the body; they abstracted heat rapidly. No unfavorable results followed their use. When the temperature fell to 104.5° and 104° F., consciousness would return. In one case, despite the fact that the young man brought up a little "black vomit," he recovered. In another case, that of Dr. Allan, then port surgeon to the Pacific Mail Steamship Company at Panama, his temperature, despite the ice pack, rose to 107° F., when he died.

In this article I have not dwelt on the cases assuming a typhoid character. They are of the classic type—initial fever, period of calm, and secondary fever. The so-called typhoid symptoms develop anywhere from the ninth to the twelfth day. These are obstinate cases. Fortunately they are the exception to the rule.

In view of the blood changes and the many tissue changes dependent upon degenerative causes, convalescence is very tedious. Extreme care has to be exercised. Frequently the convalescents have a ravenous appetite. Errors in diet must be guarded against. A full meal of beefsteak killed a man in Panama; he had his own way, and it killed him.

Meat broths, milk, and soda water, etc., are ample until the stomach has recovered its tone. Time and great patience are very necessary. Weeks and sometimes months are necessary to rebuild.

To review the matter, the cases of mild yellow fever consisted of a single paroxysm or access. They entered on convalescence. Frequently even in mild cases convalescence was very slow.

Occasionally a severe case would expend itself in a single paroxysm, when the patient entered on convalescence.

The malignant cases were fatal.

Some of the severe cases ran through all the stages, and entered on convalescence anywhere from the ninth day to the twelfth day. I can only repeat my statements: there are no fixed rules in such cases, the order of symptoms is not regular—the case depending on the man and his previous health and habits. While many young men of excellent life and habits fell victims, occasionally one escaped, thanks to his having been abstemious. I recall recoveries in four desperate cases. All the patients had been in grave peril; one had black vomit. Practically they had been total abstainers.

The period of incubation in yellow fever is a vexed one. No cast-iron law covers it. Three to six days are ample. I knew of a case in which it was all of fifteen days.

The stranger within the tropics drifts into danger, without knowing it. In many of the places the fever is endemic—at Colon, Panama; at Vera Cruz and Mazatlan, in Mexico; at Havana and Santiago de Cuba; at San Juan de Porto Rico, and at Rio de Janeiro, Brazil.

The new comer enters on a new scene, where all is strange to him, including the atmospheric and other terrestrial conditions—excessive heat and excessive moisture, rapid growth in vegetable life and rapid decay; hence exhalations from the earth's surface. He may have lived a perfect life in a temperate or northern climate; when under his usual conditions his internal organs did their work well. The natural equipoise was maintained. Heat and moisture tax the new comer. Nature tries to adapt herself, but it means a serious tissue change. In the tropics his liver becomes rebellious. The hitherto nice balance of power within is upset. The liver has additional work to do.

Many thoughtlessly expose themselves to the hot midday tropical sun. Again, others expose themselves to the excessive tropical dews. Some use liquor and malt; others have a surfeit of delicious tropical fruits, matured on the trees and stalks. The matured fruit juices add to general stimulation. A fever of some kind is a mere question of time. If yellow fever is active at the time, generally it is yellow fever; or it may be a simple malarial fever, a bilious remittent, or a pernicious malarial fever. Malarial fever gives no protection, none. The fact must be borne in mind that healthy men and women are its principal victims.

An attack of yellow fever protects against subsequent attacks.

In all centres where the disease is endemic—such as Panama, Cuba, and Mexico—at certain seasons if the material is present, unacclimated people, epidemics are in order.

At Panama during the work on the Panama canal, some very interesting and instructive work was done by my brother, the late Dr. George W. Nelson. He was resident physician at the canal company's hospitals. He had sets of self-registering dry and wet bulb thermometers, as well as a self-registering barometer. Within the hospital grounds was the fever hospital. While yellow fever was epidemic, the thermometric and barometric tracings were carefully noted. A hot dry wave would be in order, when new cases of yellow fever would develop among the employees. The hot wave would end in rain, accompanied frequently by tropical thunder and lightning. The result was marked, both among the yellow-fever patients in the canal hospital and in the city of Panama. With the fall in temperature and general electric disturbance the severe cases ended fatally. The storm over, a few cooler days would follow, when there would be a lull; then another hot wave with new cases; again rain, more thunder and lightning, during which the serious cases again were fatal.

In another article I shall take up other facts connected with this disease.

A CHEMICAL, PHYSIOLOGICAL, AND CLINICAL STUDY OF PANCREATIC CYST FLUID (FROM THE CLINICAL LABORATORY OF THE UNIVERSITY OF MARYLAND).

By JOHN C. HEMMETER, M.D., Ph.D.,

CLINICAL PROFESSOR, MEDICAL DEPARTMENT, AND DIRECTOR OF THE CLINICAL LABORATORY,

AND

HARRY ADLER, A.B., M.D.,

INSTRUCTOR IN CLINICAL PATHOLOGY.

(With a clinical report of the case by L. M. Tiffany, M.D., Professor of Surgery.)

The pancreatic cyst fluid furnished by Professor Tiffany was shown to be perfectly sterile; cultures attempted on agar, peptone, gelatin, and bouillon were negative. The specific gravity of the liquid was 1.028. It had a chocolate color, and on standing a light gray deposit separated from the dark reddish-gray supernatant liquid. Total quantity received, 980 c.c. It had a neutral reaction.

The chemical and physiological studies were made by Dr. Hemmeter; the histological study was made by his associate, Dr. Harry Adler.

Experiments were made with artificial digestion of proteids, carbohydrates, and fats, and the effects on the curdling of milk and varying quantities of the pancreatic cyst fluid. In testing the digestive power for proteids, sterile blood fibrin and discs of boiled egg albumen were employed.

For testing the amylolytic power we employed freshly prepared sterile starch paste (one per cent.). In the experiments for determining whether the cyst fluid contained any fat splitting or adipolytic ferment (steapsin), we made use of weighed quantities of sterile neutral olive oil.

All of the quantitative digestion experiments were made under aseptic precautions, and test cultures were made from the digesting-mixtures before they were placed in the incubator and after they were removed from it.

The liquid was examined for sugar, albumin, peptone, bile acids, and xanthin bodies, prior to the digestion experiments.

Sugar was absent in the fermentation and reduction tests.

Bile acids were found to be absent.

Albumin, propeptone, peptone-globulin, etc. Fifty cubic centimetres of the fluid was rubbed with Na_2SO_4 in excess; a deposit of globulin resulted. The mixture was filtered. In the filtrate a deposit of albumin occurred on boiling with nitric acid, showing presence of albumin. Ten cubic centimetres of the liquid was acidified with acetic acid, boiled, freed from albumin, and filtered. In the filtrate the biuret reaction could be detected; this meant either propeptone, peptone, or both. Ten cubic centimetres of the fluid was rubbed up with excess of ammonium sulphate; freed from propeptone and albumin, the filtrate gave no biuret tests. This indicated that peptone was absent. Albumin, globulin, and propeptone were present; sugar and peptone were absent.

Xanthin bodies. Twenty cubic centimetres of cyst fluid freed from albumin was made alkaline by ammonia, and, after removal of the phosphates, treated with ammoniacal silver solution. No precipitate occurred; hence free xanthin bodies were absent. Latent xanthin bodies were found to be absent also.

Determination of Solid Residue.—December 20, 1897. Weight of evaporating-dish, 23.9346.

Ten cubic centimetres of pancreatic cyst fluid evaporated on water bath.

Weight of dish and evaporated fluid, 24.352.

Weight of evaporating-dish alone, 23.9346.

One cubic centimetre pancreatic cyst fluid contained 0.4174 mgm. solid residue. Dr. Adler found that the cyst fluid contained ten parts of albumin to the thousand, as determined by Brandberg's method.

According to Esbach's albuminometer, it contained almost eleven parts to the thousand. The presence of blood pigment was shown by the turpentine-guaiacol test and the finding of Teichmann's hæmin crystals on treating with salt and glacial acetic acid.

The conversion of proteid into peptone and of carbohydrates into maltose and dextrose, and also the breaking up of fats into fatty acids and glycerin, will occur under the influence of certain bacteria in the entire absence of unorganized ferments.

In a patient who had received an abdominal injury, having been so horned by a steer that the gastric juice, together with the bile, pancreatic juice, and succus entericus ran out through a fistula, Busch observed that coagulated albumin became dissolved when it was lowered into the intestine, inclosed in gauze bags, which could be withdrawn through the fistula at will by a thread.[1] In this patient there could not possibly have been any secretion in the digestive canal, so that the digestion of proteids can be attributed only to bacteria. In almost all of the experiments conducted by the other observers, cited in this article, no precautions were taken to have the digesting-mixtures sterile. The co-operation of the bacteria in the solution of proteid can therefore not be excluded in these cases. If we therefore desire to find out the digestive power of the pancreatic cyst fluid, *per se*, sterile digestive mixtures are indispensable. As will be seen later on, the cystic fluid presented by Professor Tiffany exhibited marked proteolytic, amylolytic, and adipolytic properties. Most of our digestive mixtures were kept sterile, but others were intentionally infected with pure cultures of the lactic-acid bacillus, the bacillus lactis aerogenes, the colon bacillus, and the bacillus of typhoid fever, and some were permitted to become infected in a general way by exposure to the air. These latter were found to be later on infected predominantly with staphylococci.

There is no doubt that widely differing conditions have been described and classed under the head of pancreatic cysts. According to Virchow, accumulations of liquid in the immediate vicinity of the pancreas, which originally were in no direct causative relation to pancreatic disease, have been classed erroneously as pancreatic cysts. In the surgical literature of the subject one finds almost exclusively reports concerning the simple cysts only; there are undoubtedly multiple cysts also. While the prevailing opinion is that these cysts are caused by stenosis of the duct of Wirsung, by cicatrices, calculi, or invasion of ascaris lumbricoides (Durante); furthermore, through neoplasms arising in the pancreas itself or in the adjacent organs; and while these were considered the only and most important cause of retention cysts—O. Madelung[2] maintains that this mode of causation is comparatively rare, a part of the cysts arising from inflammatory processes of the interstitial glandular tissue (abscesses and purulent cysts), another part from hemorrhages in consequence of traumatism (apoplectic cysts). A portion of the cysts arise through foci of softening in solid neoplasms, such as carcinoma and sarcoma. According to Garrigues, Petrykowski, and Roux, proliferating cysts or cyst adenomata of the pancreas may occur.

Concerning the Diagnosis.—The clinical picture and the position of the cyst, as well as its relation to the surrounding viscera, will depend upon the part of the gland from which it originates; the origin from the tail end of the pancreas appears to be the most frequent. The retroperitoneal cysts as they enlarge push into the bursa omentalis, and when they have filled this out force their way through the foramen of Winslow into the greater peritoneal cavity. The stomach lies above such cysts, the transverse colon and the mesocolon are below, and the gastrocolic ligament is in front of them. In rare instances the cyst grows more superiorly than anteriorly. In this instance the hepato-duodenal ligament is arched forward and the stomach is displaced downward (Riegner). When the cysts grow between the layers of the transverse colon and the mesocolon and the superior layer is arched forward, the transverse colon may be dislocated downward. Schoenborn has reported a case in which the transverse colon passed diagonally across the highest portion of the tumor. v. Hacker and Hersche have reported similar cases. Madelung asserts that pancreatic cysts which have exceeded a certain size and descended deep into the inferior peritoneal cavity, cannot be distinguished from ovarian cysts, except by laparotomy, and even then it is possible only during the extirpation. As important points for the diagnosis he gives the following: origin of the tumor in the superior portion of the abdominal cavity, colicky pains in the epigastrium or left hypochondrium, various intense dyspeptic symptoms, and characteristic state of the stools. Evidence of a cystic tumor in the region of the pancreas, the lower convex edge of which is palpable, and the greatest extent of which from above downward is found to be in the parasternal or mammillary line. From here the dimensions of the tumor suddenly diminish toward the left axillary line; the cyst can be outlined by the absence of tympanitic resonance on percussion. It shows a slight rising pulsation and slight respiratory mobility. Mellituria and stearrhœa as well as brown skin have been observed in rare cases.

Madelung attributes the diseased digestion not to impeded digestive activity through absence of pancreatic juice in the intestine, but to compression of the stomach and intestines; this is also his explanation for the rapid emaciation. In view of the fact that other abdominal tumors, of non-malignant type (pregnancy, etc.), may also compress the stomach and intestines considerably without causing this rapid emaciation, the writer (Hemmeter) is disposed to believe that the imperfect utilization of proteids, fats, and carbohydrates in cases of pancreatic cysts is due to the absence of pancreatic secretion from the duodenum.

Rate of Growth.—The time in which the present cyst developed could not be determined: the patient complained only three weeks. Some cysts reach the size of a man's head within a few weeks; others require a very long time. Riedel reports a case developed in nine years. Salzer, one requiring fifteen years; and Martin, one requiring more than thirty years before the growth assumed considerable dimensions. Some cysts have very thin and friable walls; Beckel, however, reported one having a wall one-half centimetre in thickness.

Capacity.—Riedel's case had a capacity of 10 litres; Bozeman, 11.5 litres; Park, 14 litres; Martin, 15

[2] Penzoldt and Stintzing: "Handbook," vol. iv., p. 212.

litres. In these large cysts the contents did not show the characteristics of normal pancreatic secretion. This may be attributable to the fact that in old cysts the ferments have either been destroyed or entered into combination with the albuminous and other digestible substances contained in the cystic contents.

Results of Examination by Puncture or Aspiration.—In reviewing the literature of the subject, one cannot fail to be impressed with the fact that the results of examination of fluid obtained by aspiration have not come up to expectations. In a majority of the cases the aspirated fluid did not show the proteolytic, amylolytic, and adipolytic properties of pancreatic juice. Senn and Kulenkampf obtained a fluid clear as water, which led them to suspect the presence of an echinococcus cyst; and Kotz obtained a liquid with marked bloody admixture, leading him to suspect an ovarian cyst.

It might be presumed that when a pancreatic cyst is tapped under strictly antiseptic precautions, no harm could ensue even if some of the fluid escaped into the peritoneum. This view was held by Senn, but the experiments of Hildebrand and Rosenbach-Jung have demonstrated that escape of pancreatic fluid into the peritoneal cavity may produce fat necrosis. Rosenthal, Cathcart, and Tremaine have reported cases in which the entrance of cystic fluid into the peritoneal cavity caused collapse and compelled a speedy laparotomy. Kuester and Kocher reported cases in which symptoms of peritonitis were produced, and in Socin's case death was attributed to entrance of the cyst fluid into the peritoneal cavity. As it is possible that the stomach or colon may be pushed between the pancreatic cyst and the abdominal walls, and that when adhesions exist between the cyst wall and the stomach it is impossible to determine to what extent the stomach may be in contact with the anterior abdominal wall even when the stomach is artificially distended, it is intelligible how the trocar may be pushed through the stomach or intestines in the efforts to reach the cyst. In Dixon's case the cyst refilled exceedingly rapidly after it had been evacuated by puncture, and several punctures did not produce a cure in Steele's case.

It cannot be the object to consider the treatment in connection with this study. The treatment, which is mainly surgical, will be found described in the new text-books on abdominal surgery.[1]

One of the most marked and constant symptoms is rapid emaciation. Küster reported a case in which there occurred a loss of fifteen kilograms, or thirty-three pounds, in four months. Leube holds that colicky pains in the gastric region do not occur in connection with other cystic tumors in the upper portion of the abdomen.

The diagnosis must exclude echinococcus cysts of various abdominal organs, dilated gall bladder, hydronephrosis, and ovarian cysts. As far as could be determined from the literature, a positive diagnosis of pancreatic cyst in women has never been arrived at. Diastase is found in all the fluids of tissues; hence this has no diagnostic significance. The following table[2] illustrates the diminution in the solids, organic substances, and ashes which occurs in the fluid discharge from a permanent pancreatic fistula. The juice from a temporary fistula is much richer in these constituents.

Juices from Temporary Fistula.			Permanent Fistula.		
Water	900.8	884.4	976.8	979.9	984.6
Solids	99.2	115.6	23.2	20.1	15.4
Organic substances	90.4	....	16.4	12.4	9.2
Ashes	8.8	....	6.8	7.5	6.1

[2] C. Schmidt, nach Maly: "Chemie d. Verdauungssäfte." Hermann's "Handbuch," Bd. v., Theil 2, S. 189.

Christ. Dieckhoff[1] distinguishes between (1) retention and (2) proliferation cysts; of the latter only one typical case has been reported.

Tilger[2] stamps the so-called hemorrhagic cysts as "theoretical assumptions."

Nimier[3] believes that pancreatic cysts may arise from hæmatoma, in which a simultaneous tear has occurred into the duct.

As a result of experiments upon animals, Senn has been led to the opinion that a damming back of the pancreatic secretion, with consequent formation of a retention cyst, is possible only when, in addition to closure of the excretory duct, there is at the same time an alteration in the glandular tissue of such a nature that a resorption of the secretion cannot take place.

In seventeen cases collected by Leith, a period varying between ten days and ten years elapsed after receipt of the injury before the cyst was discovered. Closure of the duct of Wirsung with resulting cyst formation may, it is claimed, be occasioned by a catarrh extending into the excretory duct from the duodenum.

Among the occasional causes are concretions, interstitial connective-tissue hypertrophy, carcinoma, cicatrices after injuries.

Leo[4] asserts that the reaction of contents is always alkaline; the sediment contains fatty and other degenerated epithelial cells; urea in one case; diastase, he asserts, is always found, and a fat-decomposing ferment. He claims to have no reports concerning the presence of trypsin.

The contents when the cysts are recent consist almost of pure pancreatic juice; later on, extravasations of blood occur, and sometimes pus, bacteria, and epithelial detritus. The bacteria may come in by way of the duct or with the primary disease causing the stenosis.

The physiological and chemical properties of the cyst fluid are not constant, and therefore not reliable diagnostically. The diastatic and proteolytic actions have repeatedly been found missing. The adipolytic action has rarely been observed, and even if a diastatic action could be discovered in an aspirated fluid it would not be pathognomonic of pancreatic cyst, as many other animal fluids possess a diastatic ferment. Von Jaksch points out that the physiological properties of the normal secretion will be found missing more and more, the older the cyst is, the more dilute and altered its contents have become, and the more independently the cyst has developed from the physiological organ. This is the case with the cysts of other organs also.

Proteolysis by Pancreatic Cyst Fluid.—The solvent action of the cyst fluid was tested with coagulated blood fibrin and with boiled and fluid egg albumen.

(1) Fresh blood fibrin from the calf, ox, or sheep was washed with water until it was of a pure white color; then it was boiled repeatedly with water, and thereafter extracted with cold alcohol, boiling alcohol, and finally with ether; then it was ground in a mortar to a coarse powder, and rubbed through a sieve under uniform pressure. The particles thus obtained were generally found to be of the same size. The powder prepared in this manner was then dried at 110° C. to bring the mass to a constant weight. This entire process was done under antiseptic precautions, and the fibrin was dropped into the digestive mixture with a sterilized steel spoon.

Two grams of blood fibrin was added to 20 c.c. of

Generally an equal quantity of sterile distilled water was added to the cyst fluid; at the end of a given period the digesting mixtures were removed from the incubator and heated to boiling in a water bath to destroy the ferment. The undigested residue was collected on a filter, washed with boiling water until it was free from all soluble substances, and then dried at 110° C. The difference between the weight of fibrin originally placed in the digesting-mixture and of the undissolved residue regained constitutes a reliable index of the proteolytic action of the cyst fluid. It will be seen from the above examples, which are taken from a series of twelve experiments, that the cyst fluid digested on the average 86.93 per cent. of pure fibrin.

Digestion Fluids with Fluid Egg Albumen.—The albumen solution was prepared according to the method of Schütz.[1] The globulin was removed from a measured amount of undiluted egg albumen by the addition of HCl (s. g., 1.120)—4.2 c.c. HCl to 300 c.c. albumen. The mixture was vigorously shaken and allowed to stand for six hours, and then filtered. This solution, which must be carefully neutralized by dilute sodium carbonate, contains approximately 1 gm. of coagulable proteid to 10 c.c. of the fluid; the exact amount can be determined by precipitating with heat and collecting the precipitate on a weighed filter and drying at 110° C. The digestive mixtures were prepared in the following manner; each mixture contained 10, 15, or 20 c.c. of the prepared albumen solution, together with 10, 15, or 20 c.c. of the pancreatic cyst fluid. The flasks or test tubes were placed in the incubator and kept at 38° or 40° C. from six to eight hours. The digestion was arrested at any desired time by placing the mixtures in boiling water to destroy the ferments; the unaltered albumen was precipitated, collected on a weighed filter, washed with boiling water, and dried at 100° C. The difference between the amount of coagulable albumen originally used and the amount regained at the end of the experiment gave the amount of the soluble digestive products; in this way it was possible to measure the degree of the proteolytic action of the pancreatic cyst fluid with fluid egg albumen. In other experiments we did not use this albumen solution, but simply weighed amounts of ordinary hard-boiled egg white, and determined the degree of proteolysis by weighing the amount of albumen recovered.

[1] Zeitsch. f. physiol. Chem., Bd. ix., p. 581.

EXPERIMENT No. 5.

Amount of Albumen.	Amount of Cyst Fluid in c.c.	Undigested Albumen in gm.	Per Cent. of Proteid Digested.
1.639 gm	10	0.925	88.8
1.639 gm	20	0.547	66.8
0.8199 gm	30	Trace.	100

EXPERIMENT No. 6.

Boiled Solid Egg Albumen.	Amount of Cyst Fluid in c.c.	Undigested Albumen in gm.	Per Cent. of Proteid Digested.
2 gm	20	0.5834	70.9
2 gm	10	0.2863	71
2 gm	20	0.2601	87

From these experiments, which are examples from twelve analyses, we concluded that the pancreatic cyst fluid will digest 83.6 per cent. of the fluid albumen solution made according to Schütz, and 76.3 per cent. of boiled egg white.

Experiments Concerning the Amylolytic Action.—The products formed from starch by diastase are in the main amylodextrin, erythrodextrin, achroodextrin, and maltose. The first stage of transformation is soluble starch or amylodextrin; this still gives a blue color with dilute solution of iodine. As the diastatic action proceeds, the blue color gradually gives place to a purplish-red color with iodine, the red purple being due to the formation of erythrodextrin. The end products of amylolysis, achroodextrin and maltose, give no color reaction with iodine; thus the color obtained under these conditions is dependent upon the amylolytic action. The stage at which the digesting mixture gives no color with tincture of iodine is called the "achromic" point, and the number of minutes required for the achromic point is an index of the intensity and rate of amylolytic action.

There are two ways of determining approximately the rate of amylolysis: (1) One is by determining the achromic point; (2) the second is by determining the amount of maltose formed by the method suggested by Allihn.[1] From the amount of copper reduced when the solution to be analyzed is boiled with a standard Fehling's solution freshly prepared, the amount of maltose was calculated. Salomon has shown that one hundred parts of anhydrous maltose will reduce one hundred and fourteen parts of copper when boiled with standard Fehling's solution.[2]

The Diastatic Action of Pancreatic Cyst Fluid Determined According to the Time of Appearance of the Achromic Point.—In all of these experiments a one-per-cent. solution of freshly prepared starch paste was used. This was mixed with varying quantities of pancreatic cyst fluid, and sometimes diluted with sterilized water, and placed in the incubator at 38° or 40° C. In determining the achromic point, the time at which the cyst fluid was added was accurately noted. A drop of the digesting-mixture was withdrawn at intervals and tested with a drop of dilute iodine solution on a white porcelain surface. This method can, of course, inform us only of the time when all the starch has been transformed into achroodextrin and maltose. The exact amount of maltose it is impossible to obtain except by the method of Allihn.

EXPERIMENT No. 1.

Amount of Cyst Fluid.	Amount of 1 Per Cent. Solution of Starch, c.c.	Time of Appearance of Achromic Point, min.
10 c.c.	10	8
20 c.c.	20	10
5 c.c.	10	8
1 c.c.	10	8
1 drop	10	10
1 drop	20	10
1 drop	25	11
1 drop	22	10 and 10 sec.

[1] Zeitschr. f. analytische Chemie, Bd. xxii., p. 48.
[2] Journal für praktische Chemie, Bd. xxviii., p. 109.

Experiment No. 5.

Amount of Cyst Fluid.	Amount of 1 Per Cent. Solution of Starch, c.c.	Time of Appearance of Achromic Point, min.
1 drop	30	15
1 drop	50	30
1 c.c.	50	10
10 c.c.	50	10

The rest of the experiments concerning the time of the appearance of the achromic point gave the same evidence of a remarkable amylolytic action of the cyst fluid, one drop of the fluid bringing on the achromic point with 10 c.c. of one-per-cent. solution of starch in ten minutes.

By the method of Allihn above referred to, the amount of maltose formed was ascertained by the amount of copper reduced in Fehling's solution.

One gram of arrowroot starch was made in a paste with the amount of water varying from 30 to 50 c.c. The cyst fluid was then added to bring the amount of the total fluid up to 50 c.c.; the mixture was then placed in the incubator at 38° to 40° C. for one hour; the solution was then heated to boiling to prevent further action of the amylopsin. The solution, after the digestion had been arrested, was diluted to 120 c.c. with sterile water, and the degree of amylolytic action ascertained by determining the amount of maltose in 20 c.c.; the 20 c.c. containing one-sixth of a gram of starch.

Experiment No. 3.

Amount of Cyst Fluid.	Amount of Starch, gm.	Amount of Copper Reduced in ½ gm.	Per Cent. of Maltose Formed.
10 c.c.	1	0.0908	39
10 c.c.	1	0.0910	31.96
20 c.c.	1	0.144	75.8
20 c.c.	1	0.146	75.5

Six other experiments, made to determine the maltose formed by Allihn's gravimetric method, give evidence that 20 c.c. of the cyst fluid will form about 75 per cent. of maltose from one gram of starch at a temperature of 38° C.

Experiments Concerning the Adipolytic Action of the Cyst Fluid.—Ten grams of neutral olive oil was mixed with 10 c.c. of cyst fluid; the reaction was neutral, perhaps very slightly alkaline. As a control test, 10 c.c. of neutral olive oil was shaken with 10 c.c. of sterile distilled water, and both mixtures were placed in the incubator, at 38° to 40° C. The degree of adipolysis was determined with the Soxhlet apparatus, according to Müller's method.[1] The digesting-mixtures were kept in the incubator for twelve hours, when they reacted strongly acid; the control mixtures containing simply oil and water still reacted alkaline. The titration for free fatty acids, using phenolphthalein as an indicator and an alcoholic decinormal solution of potassium hydroxide, showed that from 12 to 14 per cent. of free fatty acids had been formed.

Spectroscopic Examination.—The cyst fluid itself, as well as an HCl-ether extract made therefrom, showed a broad band between Fraunhofer's lines D and E in the yellow and green; it is therefore probable that the coloring matter is hæmatin. According to W. G. Halliburton and T. T. Burton,[2] pancreatic juice possesses a milk-precipitating substance, causing at 35° to 45° C. a granular precipitate in milk; but there is no solidification until the milk cools, when it sets to a coherent curd; on warming, the curd is broken up and the milk resumes its granular fluidity. The precipitate seems to be a body intermediate between casein and caseinogen. We made several tests with the cyst fluid and milk to detect such an action if present; the tests were all negative, showing an absence of the milk-precipitating substance.

Microscopic Examination of Cyst Fluid.—The sediment of the fluid was shown under the microscope to consist of an amorphous granular detritus and several distinct morphological elements.

(1) Pavement epithelial cells in large numbers were to be seen, some presenting an almost normal appearance, being of a quadrilateral shape and containing a distinct oval nucleus. But by far the large majority had undergone fatty degeneration and partial digestion. It is probable that the amorphous detritus was formed largely from these broken-down cells.

(2) Hæmatoidin crystals arranged in radiating clusters of an orange color were present.

(3) A very few cholesterin crystals.

(4) The remainder of the morphological elements consisted of two forms of hyaline translucent bodies. Of these the greater number were irregularly round, varying in size from 3μ to 10μ. Much fewer in number were slender hyaline bodies, having a swelling at either end resembling dumbbells in appearance. Sometimes there was a third swelling in the middle. These varied in length from 4μ to 16μ. Both forms of these bodies acted similarly to reagents. They did not stain with methylene blue, eosin, or osmic acid. They stained slightly with hæmatoxylon and deeply with carbolfuchsin (Ziehl's solution). Iodine did not color them. They were not dissolved by dilute acids or alkalies, alcohol or ether. Alcohol and chromic acid produced no turbidity, distinguishing them from mucus. These bodies belong, therefore, to the class of the so-called colloid bodies.

The tissue which was cast out of the abdominal fistula after the aspiration was irregular in shape. It was 12 cm. long, 4 cm. at its widest part, and from 5 to 8 cm. in thickness. It weighed, moderately wet with seventy-per-cent. alcohol, 12.5 gm. Scattered irregularly throughout the tissue were dark pigmented portions. Sections were made from several different parts. These, on being stained with hæmatoxylon and eosin, stained diffusely red. Under the microscope they were shown to consist mainly of white fibrous tissue. At some places the fibres lay in parallel bundles and presented a nearly normal appearance; at others they appeared separated and broken down. Among these fibres, scattered over the specimens, was a varying amount of hæmatoidin crystals. Also, lying among and distributed irregularly through the sections, were round bodies, semitranslucent and only very slightly stained blue with hæmatoxylon. They varied in size from 3μ to 40μ. They were not affected by dilute acids or alkalies, nor by alcohol or ether. With iodine they stained very slightly yellow. They are therefore in all probability colloid material. At the periphery of sections taken from one part of the tissue there was an area of dense infiltration of leucocytes. The majority of these were of the polynuclear variety. In nearly all the sections could be seen at one border a distinctly glandular structure made up of columnar cells. These cells were for the most part arranged in the form of acini, so that the glandular nature of the cells was unmistakable. The nuclei of the cells were mostly in the centre, but a few cells could be seen in which the nuclei were at the base. The cells were granular, like those of a serous gland. That it was a portion of the pancreas is rendered highly probable by the granular nature of the cells and their nuclei being centrally situated.

History Given by Dr. Henry F. Hill.—I first saw Henry D—— with Drs. Hill and Chew, on December

[1] Leo's "Diagnostik d. Krankh. d. Bauchorgane," p. 343.
[2] Journal of Physiology, p. 106.

5, 1897, which was the twenty-seventh day of his (H. D——'s) illness. Dr. Hill gave me the following history:

"Henry Dixon, aged twenty-four, male, white, robust build, car conductor, had always enjoyed excellent health. While on his way to take his car out, he was seized with cramps in the epigastric region, which compelled him to return home. Vomiting soon began, and both pain and vomiting continued for four or five days almost incessantly, notwithstanding one-tenth grain calomel tablets were given, and later sulphate of magnesium. There was no rise of temperature or acceleration of pulse. The patient complained of fulness, as though he would burst, in the region of the stomach; here he was tender on pressure. After the first week the patient became better, though confined to bed, and sat up during the second week, but he was nauseated and was constantly spitting. He went downstairs during the second week. There was no jaundice at any time. On the fourteenth day he went out of doors, and during the third week returned to his car and worked for a few days, though not feeling perfectly well. On the twenty-first day after the commencement of the sickness I was called to see the patient, and found him vomiting a good deal, with return of pain over the stomach. The following day (twenty-second of his sickness) I discovered some dulness to the left of the median line over the spleen, but it was not pronounced. On the twenty-third day dulness increased, and I marked its outline with ink. The twenty-fourth day dulness rapidly increased; but the temperature was only one degree above normal and the pulse less than 90. On the twenty-fifth, temperature, 99.4° F.; pain present, of a dull character; and the swelling was perceptible to the eye, having increased much. Dr. Chew was requested to see him, which he did next day—Saturday, the twenty-sixth day of illness. The following day Dr. Tiffany was in consultation."

Clinical History by Dr. Tiffany.—I saw H. D—— with Drs. Chew and Hill, December 5, 1897, and received the history already detailed by Dr. Hill. Physical examination showed a swelling in the epigastric region, rather more to the left of the middle line than to the right, firm, elastic, rounded, dull on percussion, continuous with the hepatic and splenic dulness. At the extreme upper border resonance was evident, presumptively of the stomach; across the lower portion a certain amount of resonance existed, presumptively of the colon. The swelling was 13 cm. across, by nearly the same diameter vertically; on percussion over it a certain thrill was elicited; it did not move in respiration, not even in forced respiration, and seemed to pass backward into the kidney region. It was undoubtedly cystic. The urine and stools had been normal and the temperature scarcely elevated above normal at any time. Respiration was not changed. The patient rested well upon the back. The same day he entered hospital, and the following day, December 6th, I operated.

Under ether an incision was made in the linea alba over the swelling, 14 cm. long, and the peritoneum opened, which was healthy; the lower border of the stomach and the transverse colon presented with the swelling behind. The omentum between the stomach and colon was torn through, and the tumor came into view. The cyst wall was uncovered over an area of 5 by 3 cm., and the denuded space packed with gauze. No reaction followed the operation, and two days later the cyst was tapped with the usual precautions for cleanliness, and the fluid received into a clean bottle, which was given to Dr. Hemmeter for examination. The amount of fluid withdrawn was about one and one-half quarts. All went well. The drainage tube was left in the sac, and was subsequently replaced by gauze. The sac granulated rapidly and the patient left hospital at the end of a month, a small sinus only remaining. Ten days after the sac was opened there was withdrawn by the resident physician from the sac a mass of slough, which presented at the opening. It was 10 cm. long by 4 cm. broad at one end, tapering to a point at the other. From the examination herewith annexed (Dr. Adler) it would appear to be a portion of the pancreas.

OBSERVATIONS ON MORTON'S PAINFUL AFFECTION OF THE FOURTH METATARSO-PHALANGEAL ARTICULATION AND SIMILAR AFFECTIONS OF THE METATARSAL REGION THAT MAY BE INCLUDED WITH IT UNDER THE TERM ANTERIOR METATARSALGIA.[1]

By ROYAL WHITMAN, M.D.,

NEW YORK,

INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; CHIEF OF THE ORTHOPÆDIC DEPARTMENT OF THE VANDERBILT CLINIC; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

In 1876 Dr. T. G. Morton, of Philadelphia,[2] described a series of cases characterized by recurrent pain about the fourth metatarso-phalangeal articulation. The pain was usually sharp and cramp-like in character. It was at first localized at the affected joint, but unless it was checked it increased in intensity and extended to the other toes, to the dorsum of the foot, and leg. The cramp might be relieved in most instances by removing the shoe and by rubbing and compressing the painful part.

The pain was ascribed to pinching of the external plantar nerve or its interosseous fibres, by the adjoining fourth and fifth metatarsal bones. The location of the pain was explained by the peculiar distribution of the external plantar nerve, which predisposed it to injury; by the relative shortness and mobility of the fifth metatarsal bone, which allowed it to roll above and under the fourth, the head and the base of its adjoining phalanx being thus brought into contact with the head and neck of its fellow. As a result of the bruising or pinching, neuritis followed.

The original cause of the abnormal mobility, or of the condition that allowed the pressure, in many instances was injury, possibly rupture of the transverse ligament; in other cases the pain appeared to be caused by tight shoes; in others no cause could be assigned. The description of the symptoms was graphically sketched in the words of the patients themselves, and no amendment is needed, except that the cases described were of a more severe and disabling character than is usually seen at the present time.

The treatment recommended and applied in a number of the cases was the removal of the head of the fourth metatarsal bone, in order to relieve the nerve from pressure, an operation that was successful in all the cases in which it was employed. In a later paper[3] Morton stated that the affection was familiar to shoemakers, and that the milder cases might be relieved by wide, thick-soled shoes and by the use of a narrow flannel bandage drawn snugly about the metatarsal region.

In 1891 Bradford, of Boston, described sixteen cases of Morton's neuralgia of a milder type.[4] Bradford accepted Morton's theory absolutely, or, as he stated, "took it for granted that the pain was entirely due to an irritated condition of the external plantar nerve caused by pressure." Yet in none of the cases was he obliged to perform resection, in none was the affection due to injury, and in none was flatfoot present. In all but one of the cases the pain was at the fourth metatarso-phalangeal articulation. The cases were treated by rest, by external applications, and by wide-soled shoes, and all appear to have been relieved or cured.

Two years later T. S. K. Morton, of Philadelphia, reported six cases of the severe type,[1] all of which had been treated by resection of the head of the metatarsal bone. He stated that he had not been able to demonstrate any laxity of the transverse ligament or other abnormal condition at the operation. He believed the etiological factors to be injury, heredity, excessive exercise, changing from a thick to a thin soled shoe, and the like. The immediate cause of the symptoms was bruising of nerves followed by neuritis. As remedial measures wide, thick-soled shoes sufficiently firm about the instep, together with the support of the flannel bandage about the metatarsus, might relieve the milder type, but advanced cases could be cured only by resection. In 1894 Gibney reported six cases.[2] He accepted Morton's explanation of its causation, but included flatfoot in the etiology. He made a valuable suggestion that the arch of the foot should be supported by a high-arched shoe made on a Spanish last; he also had relieved patients by encircling the base of the metatarsus with adhesive plaster, on the hypothesis that the heads of the metatarsal bones were thus separated.

In a recent paper by T. G. Morton,[3] illustrated by several Roentgen-ray photographs, three other cases treated by excision are reported. He states that twenty years after his first description of the affection he finds no reason to change his original opinion, that it is a painful affection of the plantar nerves, directly caused by pressure upon them or pinching them or their branches by certain portions of the fourth or fifth metatarso-phalangeal articulations.

In 1889 A. Poullosson, of Lyons, described, under the title of "Anterior Metatarsalgia," a case apparently identical in symptoms with those described by Morton and others. He ascribed the symptoms to laxity of the transverse metatarsal ligament that allowed an infraction of the metatarsal arch by the depression of the head of the fourth metatarsal bone, a subluxation that permitted lateral pressure upon the nerves distributed on either side of the bone. On this theory he had treated the patient successfully by inserting a rubber pad beneath the depressed bone. Poullosson's case was reviewed at length in *The Lancet*,[4] and the article apparently attracted considerable attention.

Roughton, in a letter to *The Lancet*,[5] reported a similar case and asserted that the symptoms "were clearly due to sinking of the anterior transverse arch and to the resulting pressure of the heads of the two or three middle metatarsal bones upon the sensitive structures of the sole of the foot."

Another writer in the same issue describes a case in which relief of symptoms always followed the pushing up of the head of a depressed metatarsal bone that could be felt in the sole of the foot.

In 1892 T. L. Guthrie[6] reported a case of anterior metatarsalgia caused by depression of the head of the third metatarsal bone, which he had treated by a pad placed beneath it.

C. E. Woodruff,[7] in a paper on "Incomplete Luxations of the Metatarso-Phalangeal Articulations," stated

[7] MEDICAL RECORD, January 18, 1890.

that anterior metatarsalgia was caused by giving way of the anterior transverse arch, owing to stretching of the transverse ligaments by long standing, injury, and the like. The disturbance of position caused pain by pressure on the digital nerves in the sole of the foot. It should be treated, therefore, by pads beneath the anterior arch.

In 1894 Goldthwait, of Boston,[1] described the anterior transverse arch and its depression as a cause of pain similar to that described by Morton, in a much more thorough and convincing manner than had been done before. His conclusions were that obliteration of the transverse arch was very much more common than depression of the longitudinal arch; that, although comparatively few persons were inconvenienced by it, yet in some instances patients suffered from pain either constant or paroxysmal, usually referred to the centre of the anterior arch, where a painful callus might be found. This location of the pain was much more common in his experience than at the point described by Morton. The causes of depression of the anterior arch were similar to those of depression of the longitudinal arch, viz., excessive standing or walking, injury, weakness after a long illness, and probably improper shoes, particularly those which were too narrow. The depression of the anterior arch might be demonstrated by an impression of the sole, which would show the absence of the re-entering angle at the base of the great toe. The condition might be relieved by placing a pad of felt or leather beneath the depressed bone or bones, or, if the affection was combined with depression of the longitudinal arch, a flatfoot brace should be employed.

In a recent paper on this subject, Jones, of Liverpool,[2] recognized depression of the anterior arch as a cause of symptoms, but he considered this to be in most instances secondary to flatfoot. The characteristic pain was not caused by pinching of the nerves, Morton's theory, because the metatarsal bones are separated when the arch is depressed; it was the result of the direct downward pressure of the misplaced bones upon the plantar nerves in the sole of the foot, practically Woodruff's theory. All of the cases were treated by resection of the head of the bone at the seat of pain, and in four instances two metatarsal bones were resected. The after-treatment was by means of thick-soled shoes, raised on the inner border as advocated by Thomas for the treatment of flatfoot, with well-fitting insteps to support the arch. Jones states that this theory of direct downward pressure on a nerve is supported by an observation of Tubby, who examined a portion of a nerve removed at an operation, and found it to be congested and swollen. It is of interest in this connection to note that Woodruff[3] described a case of what he called incomplete luxation of a metatarso-phalangeal joint, in which symptoms similar to those described were caused by a slight upward displacement of the first phalanx upon the fourth metatarsal bone. Guthrie also[4] reported a case in which intense pain was caused by overextension of the third phalanx upon the second.

A comparison of the reported cases that may be included under the term anterior metatarsalgia is of interest as bearing on the question of etiology. As no mention of other weakness or deformity is made by Morton, one may conclude that he considered the foot to be otherwise normal, yet depression of the anterior arch was present in many of the cases described by others.

In Bradford's sixteen cases the arch of the foot was normal, while in twelve of the fifteen cases reported by Jones in which the appearance of the foot was noted it was depressed, and flatfoot is considered by him to be the most important factor in the etiology.

In practically all of the earlier cases the pain was referred to the fourth metatarso-phalangeal articulation. On the other hand, Goldthwait states that the pain of metatarsalgia is much more common at other points in the anterior arch. Eight of Morton's cases were caused by injury, none of Bradford's. In all of Jones' cases, and in all those reported by the younger Morton, resection was performed, yet in the practice of Bradford, Gibney, and Goldthwait the operation had never been required.

Depression of the anterior arch is said to be the result of long standing or of overwork, yet anterior metatarsalgia is more common in women than in men. Flatfoot is alleged to be a direct cause of this depression, yet typical Morton's neuralgia is almost never a symptom of flatfoot.

As regards the actual symptoms of anterior metatarsalgia, there is little difference in the accounts of the writers on the subject, and, as has been stated already, the original description of Morton included all the important points.

The affection is relatively uncommon in hospital practice; it is more common in females than in males. Of 84 cases collected from the sources mentioned, including 21 of my own, 64 were in females and 20 in males. It is not an affection of early life, the average in 64 cases being 33 years, although in many instances the symptoms had been of long duration. As to the location of the pain, in 60 cases it was referred to the fourth metatarso-phalangeal articulation, in 6 cases to the third and fourth, in 6 to the three middle toes, and in but 6 was the fourth articulation free from pain. Of my own cases, the cramp was felt in both feet in 6, in 9 in the right only, in 6 in the left; in 14 cases the pain was referred to the fourth toe, in 3 cases to the third, in 2 cases to the second, third, and fourth, in 1 case to the second, and in 1 case to the third and fourth. In 3 cases there was marked depression of the longitudinal arch, in 3 cases slight weakness of the arch, in 2 cases an exaggerated arch, and in 13 cases the arch was normal. In 3 cases the symptoms were ascribed by the patients to tight shoes, in 3 cases to injury, in 1 case to "nervous prostration," and in 14 cases no cause could be assigned.

The pain or cramp is in some way favored by wearing a shoe; it is practically never felt at other times except in the very advanced and chronic cases. The cramp may begin as a sharp stinging pain at the fourth toe, or as a burning pain beneath the joint, or as a feeling of discomfort that gradually increases until it becomes unbearable. The pain is often intense, "like a toothache," "sickening," "like a hot coal," and the like; and unless it is relieved it spreads from the original site to the extremity of the toe, to the dorsum of foot, and up the leg. The pain is relieved by removing the shoe, and patients often wear shoes that permit removal with a single motion of the other foot. When the shoe is off the patient seizes and compresses the foot, rubs the dorsum, flexes and extends the toes, and the like. Not infrequently the cramp is preceded by a sensation of something slipping or moving in the foot, and in such instances a similar snap often precedes the relief of the symptoms. After cessation of the pain a certain soreness and discomfort remain, and at all times the affected articulation is, as a rule, sensitive to deep pressure. The cramp is induced in some instances by a misstep or sudden movement, by overextending the toes as in stooping, or simply by overexertion or long standing; but in the well-marked cases of habitual cramp no apparent cause, other than the pressure of the shoe, can be assigned ordinarily.

The affection is extremely chronic, but occasionally spontaneous recovery may take place; in such cases a

[3] *Locus cit.* [4] *Locus cit.*

particular pair of shoes receives the credit of the cure, and in reality the most marked peculiarity of the cramp is that the pain is induced by the shoe and is relieved by its removal. Minor degrees of pain of the nature of metatarsalgia must be common; Morton states that the affection is well known to shoemakers, and almost every patient that I have seen knew of others who suffered in a similar manner.

The quotations from the literature of the subject make apparent the uncertainty that exists as to the meaning of the term anterior metatarsalgia, as well as to its cause and to its treatment. If in the typical cases the foot is otherwise normal, as is implied by Morton, or if no definite cause for the symptoms can be assigned, one must accept the barren theory that the pain ultimately depends upon the anatomical construction of the foot, and content himself to remove the head of a normal bone because it serves as a point of counterpressure in pinching a nerve.

On the other hand, the theory that the pain is the result of an acquired weakness, either of structure or function, corresponds with what is known of other affections of the foot. It is therefore more reasonable and from the therapeutic standpoint a much more hopeful conclusion; for if weakness and deformity can be recognized, they may be prevented as well as cured by appropriate treatment. I shall therefore call your attention to the anterior metatarsal arch and to its weakness, as a possible cause of the affection under consideration; and I shall attempt to explain the mechanism of the symptoms and to reconcile, if may be, the apparent contradictions that the literature of the subject presents.

The metatarsal arch is, of course, not a permanent arch, for when weight is borne the heads of all the metatarsal bones are on the same plane and the arch is obliterated. The head of the third bone bears the most weight, as is shown in normal feet by a callous or thickening of the skin beneath it. The outer and inner borders of the arch formed by the first and fifth metatarsal bones are provided with special muscles to aid in balancing and supporting the weight, and normally the toes also assist the arch and relieve it of a part of the strain of walking. When the weight is removed from the anterior arch it reforms, the second and third metatarsal bones springing upward above the level of their fellows.

One notices now on looking at the sole of the foot the rounded muscular projection of the great-toe joint and at its outer side a fold or depression, indicating the highest point in the arch. By a weak or depressed anterior metatarsal arch one means that its natural resiliency is lost, the front of the foot seems broadened and flattened, and in some instances there is a distinct downward projection at its centre, the normal prominence of the great toe having disappeared. This downward projection may be the result of a loss of tone simply, or it may be a fixed deformity, so that it is difficult to raise the arch even by manipulation. In other instances the foot may appear to be perfectly normal, even in cases of typical neuralgia.

Although the arch is always obliterated when weight is borne, yet the imprint of a normal foot differs from that of one in which the arch is weakened or depressed. In the latter instance the tissues are somewhat flabby and spread out under weight, occupying a larger surface, and thus encroach upon the clear space representing the longitudinal arch. The absence of what Goldthwait calls the re-entering angle, which represents a part of the hollow between the first and second metatarsal bones, distinguishes the imprint from that of the perfectly normal foot; but imprints, like other forms of graphic demonstration, are of more service in showing evident deformity than of value in early diagnosis.

Why should weakness or depression or other abnormal condition of the metatarsal arch cause symptoms such as have been described? This has never been adequately explained. One may understand how depressed metatarsal bones pressing on the sensitive tissues of the sole, as described by Woodruff and Jones, might cause constant pain or discomfort, but it is somewhat difficult to explain intervals of comfort, lasting, it may be, for weeks, alternating with paroxysms of pain, if all varieties of the affection are to be ascribed to this cause.

In studying a disability in which some slight change from the normal condition is suspected, one must begin by an examination of the structure and function of the normal part and of its peculiarities, and it occurred to me to utilize the hand as a more convenient member for observation than the foot. The hand and foot resemble one another closely; there are, more particularly, the same anatomical arrangement of nerves and the same relative shortness and mobility of the fifth metatarsal bone, that Morton considered of so much importance in the etiology of the affection. The metacarpal arch is composed, however, of but four bones, while that of the foot has five; but, as the first metatarsal bone has never been accused of participating in the neuralgia, this difference is of less importance than it would otherwise be. The anterior arch of the hand is increased in depth by flexing the fingers; it is diminished by hyperextension of the fingers; that is, on hyperextension the heads of the metacarpal bones become prominent in the palm, the middle bones being on a somewhat lower plane than the other two. If the relaxed hand is squeezed or compressed laterally, it will be noticed that the anterior metacarpal arch is increased in depth, the hand is as it were folded together, the heads of the third and fourth metacarpal bones project on the dorsal surface, and compression causes no pain. If, however, the fingers are held in an attitude of hyperextension, so that the arch is depressed and fixed and the hand is thus not allowed to fold together (Fig. 1), firm lateral pressure causes great pain at the junction of all the metacarpal heads. Or, if one extended finger is forced backward (hyperextended) to its extreme limit (Fig. 2), lateral pressure on the hand causes extreme pain at or about the head of the depressed bone. If with the finger in this attitude deep pressure is made on the lateral aspect of the depressed head of the bone in the palm, a point of greater sensitiveness, representing apparently the digital nerve, can be made out. The same experiment may be made upon the normal foot with the same result. Dorsiflexion of the toes, more particularly of the second and third toes, depresses the metatarsal bones and fixes them in line, so that lateral pressure causes pain by forcing the joints against one another. Dorsal flexion of one toe forces the corresponding metatarsal bone downward and lateral pressure causes pain, always at the point of depression. If with the toe held in extreme dorsiflexion, weight is placed under the foot, the projecting bone in the sole will be found sensitive to the pressure, and by manipulation the same particularly sensitive points, apparently representing the nerves, may be made out. In the hand, the fourth metacarpo-phalangeal joint, and in the foot the fourth metatarso-phalangeal joint, will be found to be most sensitive to these manipulations, probably because of the greater mobility that allows the greater depression and because the pressure can be more directly applied by the external and overriding bone.

If the conclusion be accepted that depression of the anterior arch predisposes to pain on lateral pressure, even in the normal foot or hand, one may appreciate the importance of such an abnormal attitude, whether it be occasional or habitual in the foot, which

must support the weight of the body and which is often subjected to lateral pressure by the shoe.

Again, if there are distinct types of the weakened or depressed metatarsal arch, it is reasonable to infer

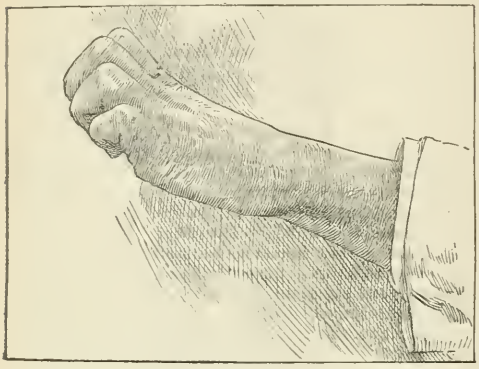

Fig. 1.

that there will be a corresponding variation in the symptoms. For example, one recognizes:

1st. A rigid depression of the anterior arch somewhat similar to rigid flatfoot, in which the front of the sole forms a general rounded prominence, in which the toes are dorsiflexed, and in which the arch cannot be reformed by manipulation. As one would expect in such cases, the pain referred to the front of the foot is more or less constant on use. It appears to be caused by direct pressure on the sensitive and depressed joints and by lateral pressure of the joints upon one another aggravated by sudden movements, which may cause pain more or less neuralgic in character, although not limited to one articulation. One case of this type seen recently had been treated previously by removal of the fourth toe and the greater part of its metatarsal bone, but without relief of the symptoms, a result that might have been predicted from the nature of the deformity.

2d. Simple non-rigid depression of the anterior arch. In this type the front of the foot is broadened on general relaxation of the tissues, and it may or may not be combined with flatfoot. In many instances the condition may exist without causing noticeable symptoms, or they may be masked by the more positive discomfort due to weakness of the longitudinal arch, but in general one would expect the symptoms caused by the increased pressure upon the heads of the metatarsal bones, the painful callus, and the burning pain beneath the joints at the centre of the arch. If, however, such a relaxed foot were subjected to lateral pressure, as from a narrow shoe, then the twinges of neuralgic pain referred to the middle of the arch or to the fourth metatarsal bone might be expected, and as a matter of fact such symptoms are complained of in a certain proportion of the cases. If the longitudinal arch is weak, the foot lengthens under use and thus affords the opportunity for lateral pressure by the narrow part of the shoe. That sufferers from flatfoot do not oftener complain of the symptoms of this lateral pressure is due doubtless to the fact that the abduction characteristic of the broken-down arch relieves the front of the foot from strain by transferring it upon the arch and inner border.

3d. Cases of typical Morton's neuralgia, in which, in many instances, the foot may appear to be perfectly normal; in others slight weakness of the longitudinal arch may be present, but more probably an effect than a cause, and in others, as has been stated, depression of the longitudinal or the anterior arch or both may be present.

In the cases in which no apparent deformity exists it may be inferred that the natural or abnormal mobility of the fifth metatarsal bone allows it to override the fourth (not to roll above and under it, as Morton suggested), and thus to cause painful pressure in the manner already demonstrated. This assumption is supported by the following evidence:

1st. Violent pain may be induced by lateral pressure on the hand when the fifth metacarpal bone overrides the fourth, but not when they are in the opposite relation.

2d. Characteristic pain may be induced in the foot by a similar manœuvre in patients who are subject to the cramp.

3d. Morton's neuralgia is often preceded by a burning pain beneath the toe, apparently due to pressure on a sensitive depressed joint.

4th. It is often preceded by a sensation of something moving or snapping and relief from pain is preceded by a similar snap.

5th. Relief is experienced by flexing and extending the toes and by compressing the foot, procedures that would tend to replace a depressed bone; and, finally, several cases are on record in which elevation of a depressed metatarsal bone or toe was a necessary preliminary to relief of pain.

One may conclude, then, that depression of the anterior arch predisposes to pain because of the weakness of its muscles and its ligaments; thus the joints and the tissues of the sole are subjected to abnormal pressure in standing and walking. Also that the depression affords the opportunity for direct lateral pressure by the shoe and by sudden movements that may

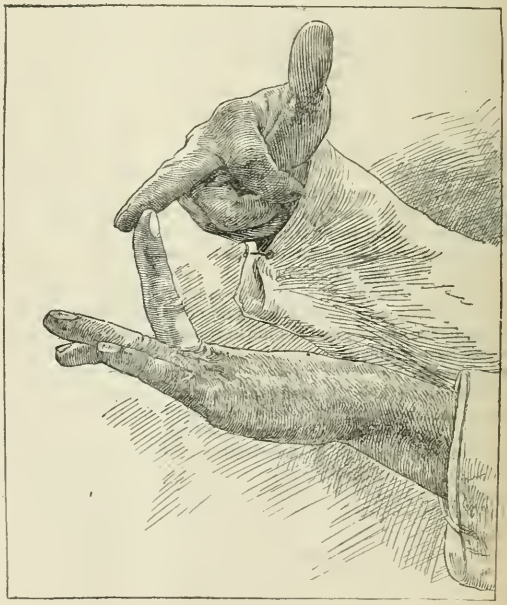

Fig. 2.

force the joints against one another. If the depression of the arch is general and equal, as in the flabby or in the fixed type, typical neuralgic pain is unusual; more often patients complain of symptoms

that are due to direct pressure on the joints, often aggravated by or entirely dependent on a sensitive callus or fibroma near the middle of the arch at the point of greatest pressure. If, however, relaxation of the parts permits one bone to fall below its fellows, then lateral compression will cause the characteristic pain. The opportunity for abnormal depression and lateral pressure is greatest at the fourth joint, because of the mobility of the fifth metatarsal bone, which allows it to assume the overriding attitude, and because of its exposed position in the shoe. For this reason typical neuralgia may be a disabling symptom although the foot appears to be normal in structure and function.

The theory that has been outlined will explain the positive effect of the shoe in the causation of the pain. When the entire arch is depressed, or when a bone in the arch is liable to displacement, the shoe may induce the cramp, because it provides lateral compression and at the same time elevates the heel, thus throwing more weight upon the front of the foot. That elevation of the heel has an influence in the causation of the pain is proved by the fact that patients subject to the cramp are usually more comfortable in walking up than in walking down an incline.

It is a common subject for speculation among patients, particularly those who suffer from occasional cramp, why one shoe is comfortable while another almost inevitably induces the pain, although the comfortable shoe may be the narrower one. The explanation is not difficult; if the tight shoe compresses the foot, as the tight glove compresses the hand, that is, folds it together, as it were, the anterior arch is elevated; but if the shoe does not support the arch in this manner and if it is still sufficiently narrow to exert pressure, or if, as is often the case, the sole of the shoe beneath the arch is curved slightly downward, one or more of the metatarsal bones, held firmly within the shoe, may be gradually or suddenly depressed below the others, and the cramp follows. Thus one may explain the onset of the pain after a long walk or sudden exertion or misstep, or even after long standing. Frequent recurrence of the cramp signifies then, displacement, pressure, irritation, and injury, that must cause a sensitive condition of the joint and of the surrounding tissues. Thus one may understand how, when the cramp habit has been acquired, very slight causes may induce the pain, and how nervous debility, weakness, or rheumatism or allied affections may aggravate its effects.

It will be noted that pressure on joints, displacement, and injury somewhat of the nature of a strain or contusion, as evidenced by the symptoms of local sensitiveness, and in some instances by local swelling and discoloration, are considered of the first importance in the explanation of the characteristics of the affection. My own observations in the dissecting-room do not support the hypothesis that the peculiar distribution of the external plantar nerve explains the location of the pain at the fourth joint. The distribution of the digital nerves and of their articular fibres is practically identical at all the joints; the pain is most often located at the fourth metatarso-phalangeal articulation because that offers the most favorable opportunity for pressure under the predisposing conditions.

If one must infer that a nerve is directly pinched by the apposed bones, it should be not a plantar but a dorsal digital nerve, as the pain is almost always felt in the dorsum of the foot and the outer side of the leg, when it is referred to more distant points. If the plantar nerves are injured, it must be by direct pressure, as Jones has suggested. Deep pressure upon the lateral aspect of the plantar or palmar surface of the joints in the foot or hand causes acute pain apparently due to compression of a nerve, as one may demonstrate upon himself; this probably accounts for the burning sensation, "the hot coal" beneath the toe, of which patients complain. At all events, direct pinching of nerves or neuritis is of secondary importance, and, in many instances at least, of very doubtful probability. Therefore, "a painful condition of the front of the foot, due to weakness and injury," would describe the affection under consideration more accurately than "a painful condition of the plantar nerves."

What are the causes of the depressed metatarsal arch or of that condition of weakness that predisposes to pain?

One form of weak arch may be due, as has been suggested, to laborious occupation, or it may be a part of a general weakness of structure or secondary to flat-foot; but this explanation does not account for the facts that the cramp is more common among women than among men and that the affection is certainly as frequent among those who are able to rest the feet as among those who are overworked, and, finally, that the pain may be an occasional or a frequent symptom when the arch appears to be perfectly normal.

It is more reasonable, it seems to me, to ascribe the affection to that most constant and commonplace cause of pain, disability, and deformity of the front of the foot, the shoe. This is not only the exciting cause of the immediate symptoms but it is the most important of the predisposing causes as well, because of its weakening effect upon the natural supports of the foot.

Under normal conditions the anterior arch should, by the assistance of the toes, be relieved from a part of the direct strain of walking, but ordinarily the toes are practically thrown out of function; they are squeezed laterally by the narrow and misshapen shoe and are lifted off the ground by what I have called the rocker shape of the ordinary sole. If, for example, a patient's hand is presented for examination, it is held with the fingers extended, but if one examines a foot he will notice that the toes are, in most instances, drawn upward and backward, that they are semi-flexed, like retracted claws, and that the range of plantar flexion is much limited. As plantar flexion elevates the anterior metatarsal arch, the test of this range of motion of the toes is of importance. If the arch is depressed and rigid, flexion of the toes is impossible, and even if it is simply depressed from weakness, the range of flexion is much restricted. In the ordinary shoe the fifth metatarsal bone almost invariably overhangs its base of support, that is, the sole, so that the fourth metatarsal bone is, in most feet, the outer support of the arch and occupies a lower level than the fifth, as may be demonstrated in the dissecting-room or upon the living subject.

This relative elevation of the fifth metatarsal bone, an attitude that predisposes to painful lateral pressure, is extremely common, and one may imagine that this elevation or abnormal position might easily be increased to the extent of causing painful pressure, although the remainder of the arch might be normal.

If one accepts the shoe as a predisposing factor in the etiology, it becomes clear at once why women, who wear shoes with narrower soles and higher heels, suffer more than men, and why the affection is as common or more common among those of luxurious habit than among those in poorer circumstances, whose ideas of beauty must be subordinated to necessity.

Anterior metatarsalgia is of course a very remote consequence of improper shoes, and the fact that distortion of the feet is so universal and yet disability so comparatively infrequent shows the reserve force and accommodative power of nature. It has even become a very general belief that the toes are relics, having at the present time no particular function, and that they are, in fact, rather a nuisance and a source of pain

than of practical value to their possessor. This belief is founded upon the erroneous idea, doubtless, that painful and distorted toes are the necessary consequence of wearing shoes.

Admitting the influence of the shoe as a cause of weakness in general and as the direct cause of the cramp in those who are subject to it, one must recognize

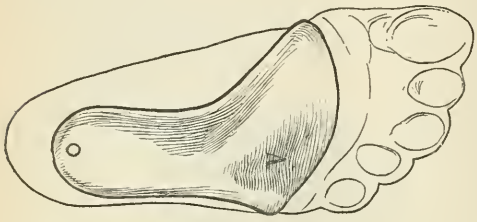

Fig. 3.

many other causes, direct or indirect, of the symptoms. For example, injury or a strain or overexertion may weaken the ligaments or increase the sensitiveness of parts already weakened. Hereditary influence appears to be of some importance, if one may trust the histories of patients. Increased local susceptibility to pain, due to gout or rheumatism or general depression of the system from any cause, may aggravate and prolong the symptoms. In fact, many of the patients appear to be of what might be called a nervous type.

Slight weakness of the longitudinal arch is not uncommon as an accompaniment of anterior metatarsalgia, but in many instances this is a secondary and not a primary condition. Direct flattening of the arch may aggravate the symptoms by affording greater opportunity for lateral compression by the narrow shoe, and, on the other hand, the exaggerated arch may increase the severity of the symptoms by throwing more strain upon the heads of the metatarsal bones.

On the theory that the cause of the pain in metatarsalgia is pressure, acting upon a depressed anterior arch or upon an arch in which a metatarsal bone is liable to displacement, one can readily explain the reason for the efficacy of the various procedures that have been advised. The wide, thick-soled shoe splints the foot, retains the metatarsal bones on an even plane, and thus prevents lateral pressure and sudden twists. The bandages and strapping about the metatarsus give relief by steadying the metatarsal bones and by supporting the anterior arch, not by separating the heads of the metatarsal bones. The Spanish arch or the foot plate is efficient because it removes a part of the weight from the sensitive joints and holds the foot firmly in one position, thus preventing its elongation in the cases in which it is actually weakened. The efficacy of pads or braces beneath the anterior arch is obvious, as is the resection of the part of the metatarsal bone against which pressure is made.

The first essential in treatment is to provide the patient with a shoe of improved pattern with a low heel, a wide, thick sole, a well-fitting arch, and with abundant room for the toes. If the foot shows a tendency toward valgus, the heel and sole may be made slightly thicker on the inner border. The main point in the direct treatment is to support the anterior arch or to prevent the attitude that predisposes to pain. In the mild cases, it may be sufficient to thicken the sole somewhat beneath the middle of the metatarsal arch, so that it may be slightly curved upward instead of downward, as is the usual construction. In most instances, however, more direct support will be required, and as an immediate treatment a pad of sole leather about one-fourth of an inch in thickness may be placed directly behind the head of the metatarsal bone of the painful joint, where it may be fixed by adhesive plaster and further secured by encircling bands of plaster about the metatarsal region. If properly applied, the direct and indirect support of the pad and plaster will almost always relieve the symptoms. In some instances, after the pad has been worn until the most comfortable size and shape have been ascertained, it may be attached to the sole of the shoe, but, as a rule, pads of this nature and the adhesive-plaster strapping, although efficacious, require too much attention and supervision. A properly fitted metal support is therefore to be preferred. This should be constructed on a plaster cast of the sole of the foot, the plaster being hollowed out just behind the affected joint, where the highest point of support should be. The front of the brace should be slightly wider than the foot, so that it may hold its place in the shoe and prevent lateral pressure; it should be extended forward practically to the end of the sole, so that it may aid in steadying the sensitive part. Behind it reaches to the heel, its centre being raised somewhat to support the arch of the foot and to strengthen the shank of the shoe. The brace is made of thin steel and it is tempered after it has been accurately fitted to the foot (Fig. 3). If the longitudinal arch is perceptibly weakened or depressed a flatfoot brace may be employed, so modified as to support the anterior arch as well. In fact, the support of the longitudinal arch, either by the shoe or by a brace, to hold the foot in place and to remove a part of the weight from the metatarsal region as well as sustain it, is a most important part of the treatment, and in many instances patients may be relieved by this means alone. When comfort has been assured by the rest and support of the sensitive part and by the avoidance of what experience has shown to be exciting causes of the pain, the patient should endeavor to strengthen the foot by exercise, as well as by proper functional use, in order that permanent cure may be assured.

The best exercise for the front of the foot is alternate flexion (Fig. 4) and extension of the toes, in order to regain a part at least of their lost function. If the metatarsal arch is rigidly depressed, it must be made flexible by daily manipulation or by forcible correction under anæsthesia before a brace can be worn and before the toes can be flexed.

I have never been obliged to perform resection.

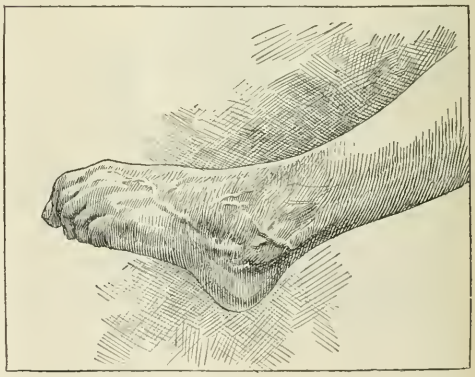

Fig. 4.

This operation is, in any event, the treatment of an effect rather than of a cause. It has the theoretical disadvantage also of weakening the foot, and it causes a rather unpleasant deformity, as the toe always recedes between its fellows; in fact, the operation is indicated only in the severe and chronic class of cases or when

proper treatment cannot be provided or has been proved to be inefficient.

If a patient were seen in the acutely painful stage of the affection, that has been described as an immediate result of injury, and if the pain were persistent at or about the anterior arch, one should assure himself that the bones were in normal position, then support and fix the arch and the foot by a properly applied plaster bandage until the acute pain and sensitiveness of the part had subsided.

It is hardly necessary to describe in detail local and palliative remedies for pain which may be indicated in special cases. Most of them will have been tried before the patient applies for treatment.

There are other painful affections of the front of the foot, in cause and symptoms somewhat similar to anterior metatarsalgia or that may be combined with it; for example, the painful callus beneath the centre of the arch. In some instances its removal will relieve the symptoms, but in most cases its underlying cause, the depression of the metatarsal arch, must be treated in the manner already described, before permanent cure can be attained.

When the longitudinal arch is exaggerated, as in the "contracted" foot, a row of painful corns beneath the projecting metatarsal bones may cause discomfort, and the condition may be accompanied by pain resembling that of metatarsalgia. In such cases, treatment must include the reduction of the corns and the correction of the equinus, if it be present.

The subluxation of the phalanx described by Woodruff appears to be practically identical in symptoms with ordinary metatarsalgia, and the subluxation is very probably preceded or accompanied by depression of the head of the metatarsal bone.

The following conclusions are presented for consideration: Morton's painful affection of the foot and the less definite symptoms that may be included under the term anterior metatarsalgia, although not identical, are nearly allied, in that an abnormal relation of the metatarso-phalangeal joints to one another, combined with pressure, is the cause of the symptoms. This abnormal relation is caused by an occasional or habitual depression of the anterior metatarsal arch or of one of the bones of which it is composed. Habitual depression of this arch is often combined with general weakness of the foot, and much of the discomfort is due to abnormal pressure on the depressed bones from beneath. Occasional and typical Morton's cramp may exist without obvious deformity, and in such instances it is caused by lateral pressure upon an overriding fifth metatarsal bone, due probably to an abnormal laxity of the ligaments. The most constant of the general causes predisposing to weakness of the front of the foot, as well as the most direct cause of the symptoms of discomfort in this region, is the improper shoe.

The cure of the condition may be attained by supporting the anterior arch, by avoiding the exciting causes of the pain, by correcting, if may be, abnormalities of structure or function, by strengthening the weakened foot by exercises, and by affording its mechanism the opportunity for functional activity by the use of a proper shoe.

Surgical Sins.—1. Operating in hopeless cases. 2. Delaying opinion as to the gravity of a disease. 3. Failure to operate in depressed fracture of the skull. 4. Pretending to be clean. 5. Undercharging in order to secure an operation. 6. Stealing patients. 7. Representing capital operations as trifling. 8. Keeping patients too long under chloroform. *Ariston metron.* Unwise speed is bad; "chronic surgery" is worse.—Emory Lanphear.

A SCHEME FOR DETERMINING THE AMOUNT OF DRUG IN EACH DOSE OF ANY PREPARATION OF THAT DRUG.

By JOHN E. GROFF, Ph.G.,

APOTHECARY IN THE RHODE ISLAND HOSPITAL, PROVIDENCE, R. I.

Many of our young medical practitioners find themselves handicapped at the very outset of their careers by ignorance of drugs and their preparations and the doses of them. To this ignorance more than to any other one thing may be attributed the extensive prescription of ready-made medicines in the form of elixirs, tablets, etc., which flood the market at the present day.

It has been the writer's pleasure to act as instructor in the particular branch of materia medica relating to the composition and strength of the official preparations and their doses, to classes of young medical graduates during their hospital training. He has long noticed that physicians prescribe the various tinctures, fluid extracts, etc., without really knowing just how much drug was represented by the amount of preparation prescribed. To illustrate: He knows three minims to be the dose of tincture of aconite root, but he does not generally know whether he may double or treble the dose, because he does not know how much aconite root is represented by each minim of the tincture; nor does he know of any general way to find out such facts.

To overcome this difficulty the writer has devised the following rules, which, with the tables given, are easily memorized and will be found of immediate and every-day value.

They have been in use for five years by both pharmacists and physicians, and the best proof of their utility is shown by the eagerness with which they are received, the readiness with which they are applied, and the continuance of their use.

I divide the commonly used drugs into three classes:

First, those given in doses of from ½ grain to 2 grains. They are aconite root, cochineal, cantharides, digitalis, opium, physostigma, and strophanthus.

The drugs of the second class are given in doses of from 1 grain to 3 grains. They are aloes, belladonna, cannabis indica, capsicum, colocynth, conium, gamboge, gelsemium, hyoscyamus, ipecac, lobelia, musk, nux vomica, pulsatilla, rhus toxicodendron, sabina, squill, stramonium, tobacco, and veratrum.

All the rest of the official vegetable drugs are given in doses of from 5 to 30 grains.

Be it remembered that dose tables are founded upon experience, and the experience of past years has had to do with improperly cared for and consequently weak drugs, and the doses were made large. The doses given above have been carefully collected from well-recognized sources, and are correct when applied to drugs answering the official requirements.

The first list of drugs should be memorized; the second need not be, but it should be read over several times, that the names in it may become sufficiently fixed in the mind to be recognized on occasion.

When a drug is to be used, one will recognize to which of the three classes it belongs, even though one do not have them at his tongue's end.

The following list of percentage strengths should be memorized:

The poisonous liquors are the arsenical liquors—Fowler's and Donovan's solutions and solution of arsenious acid. They are all 1 per cent. in strength.

The fluid extracts with one exception are 100 per cent. in strength.

The tinctures—that is, the poisonous tinctures—vary in strength and are placed in classes:

Camphorated tincture of opium, $\frac{1}{10}$ of 1 per cent.

Tincture of nux vomica, 2 per cent. of extract. (The extracts may be considered as four times the strength of the drug and the dose one-fourth as much.)

Five-per-cent. tinctures—Cantharides, strophanthus.

Ten-per-cent. tinctures—Opium, deodorized opium, ipecac and opium.

Fifteen-per-cent. tinctures—Belladonna, cannabis indica, colchicum seed, digitalis, gelsemium, hyoscyamus, physostigma, squill, stramonium.

Thirty-five-per-cent. tincture—Aconite root.

Forty-per-cent. tincture—Veratrum viride.

All the fluid preparations of opium have been made 10 per cent., excepting paregoric, the wine, and the vinegar. Also the powder of ipecac and opium.

The only poisonous official infusion is that of digitalis, the strength of which is $1\frac{1}{2}$ per cent.

Among the wines we have antimony, $\frac{4}{10}$ per cent.; colchicum seed, 15 per cent.; colchicum root, 40 per cent.; opium, 10 per cent.

When we speak of a preparation as being $\frac{1}{2}$, 1, 5, 10, or 50 per cent. in strength, we are to understand that the activity of $\frac{1}{2}$ or 1 grain, or 5, or 10, or 50 grains of drug is contained in every $\frac{1}{100}$ minims of the preparation. One minim therefore contains $\frac{1}{100}$ of that quantity. Knowing how much drug is represented by one minim, we may easily calculate how much is held in solution by any number of minims.

Example No. 1.—It is desired to give 5 grains of belladonna in the form of tincture; how much tincture must be used? By our dose table we learn that 5 grains of good drug is rather a large dose; but the tincture being a 15 per cent. tincture, there are 15 grains of drug in every 100 minims. In one minim there is $\frac{15}{100}$ of that amount, or $\frac{15}{100}$ of a grain, or $\frac{1}{6}$ of a grain to each minim. (It is between $\frac{1}{6}$ and $\frac{1}{7}$, but for uniformity we call it $\frac{1}{6}$.) In 5 grains, the amount desired, there are $\frac{30}{6}$, or the amount represented by 30 minims of the tincture.

Example No. 2.—It is desired to give 2 grains of belladonna; how much tincture represents that amount? All 15 per cent. tinctures contain 15 grains of drug in every 100 minims, or $\frac{1}{7}$ grain to 1 minim. And as there are $\frac{1}{6}$ of a grain in 2 grains, 12 minims of the tincture of belladonna will represent $\frac{1}{6}$, or 2 grains of the drug. Two minims of the fluid extract, each minim representing 1 grain of the drug, serves the same purpose. One-half of a grain of the solid extract, which is four times stronger than the drug, would also represent 2 grains of the drug, if it is desired in pill form.

Example No. 3.—The physician finds by his pocket dose list that the tincture of aconite is dosed at from $\frac{1}{2}$ to 5 minims. How much drug does that represent? The tincture is 35 per cent. in strength, or the active power of 35 grains of drug is contained in every 100 minims of the tincture. One minim contains $\frac{1}{100}$ of 35 grains, or $\frac{35}{100}$ of a grain, or $\frac{1}{3}$. Five minims contain $\frac{5}{3}$, or 1 grain and $\frac{2}{3}$. And as our drug is dosed at from $\frac{1}{2}$ to 2 grains, 5 minims are a safe dose.

From these examples it will be seen that the doctor may start out definitely. As it is, he gives 5 minims and increases or diminishes, according to circumstances, and knows not in the end how much drug he has been using. By observing these rules he always knows what he is giving.

In the same manner after a very little application, the physician may deal with all the various preparations.

A 1-per-cent. solution contains $\frac{1}{100}$ grain of drug to the minim; and $\frac{1}{120}$ grain of arsenic, or $\frac{5}{100}$, or 5 minims of Fowler's solution, are one and the same quantity.

A 2-per-cent. fluid contains $\frac{1}{50}$ grain of drug in each minim; 50 minims = 1 grain; 5 minims = $\frac{1}{10}$ grain.

A 5-per-cent. fluid contains $\frac{1}{20}$ grain to each minim; 20 minims = 1 grain.

A 10-per-cent. fluid contains $\frac{1}{10}$ grain of drug in each minim, and 1 grain or $\frac{10}{10}$ will be found in each 10 minims.

In this manner one may be exact in his dosage. If, for instance, he directs 6 minims of tincture of aconite to be given, and by mistake 12 are given, he knows just how much to worry; whereas if he knew not how many grains of drug that amount represented, he would be worried very much for several hours.

It is well to remember that both the tincture and the fluid extract of nux vomica are exceptions. The fluid extract contains $1\frac{1}{2}$ per cent. of alkaloidal strychnine, or about $\frac{1}{50}$ of a grain of strychnine to each minim. The tincture contains 2 per cent. of extract or $\frac{1}{50}$ grain to each minim. The dose of the extract is one-fourth that of the drug, or from $\frac{1}{8}$ to $\frac{1}{3}$ grain. The corresponding dose of the tincture would be from 6 to 25 minims.

It is convenient sometimes to know how much drug is represented by $\frac{1}{4}$ or $\frac{1}{2}$ an ounce or 1 ounce of a fluid preparation. The percentage strength being known, multiply by 5; the product is the approximate number of grains in each fluid ounce.

Infusion of digitalis is $1\frac{1}{2}$ per cent. Multiplied by 5, we have $7\frac{1}{2}$ grains to the ounce, or about 1 grain to the drachm.

A 2-per-cent. tincture contains about 10 grains to the ounce; a 5-per-cent. tincture about 25 grains, etc.

It was stated in the beginning that these rules have been found practically useful by quite a number of practising physicians in good standing, who use them daily; and the writer believes that if they were generally adopted until something better might be devised, they would result in a practice much more satisfactory to the physician by enabling him to attempt more, and by giving him better results through the application of known quantities.

Progress of Medical Science.

Dysmenorrhœa. — Dr. v. Oswiecimski (*Klinisch-therapeutische Wochenschrift*, June, 1898) recognizes three forms of dysmenorrhœa: 1. The inflammatory, which is due to the inflammation of the uterus itself, its adnexa, or the neighboring organs. 2. The nervous, caused by the hyperæsthesia of the uterine mucous membrane. 3. The mechanical, dependent upon some obstruction which prevents the flow of blood to and from the uterus. Under this category he mentions hypoplasia uteri, stenosis of the cervix, anteflexion of the uterus, and closure of the internal os.

Resection of the Sympathetic. — Messrs. Combemate and Gaudier, of Lille, showed a patient before the Paris Academy of Medicine at the meeting of April 19th. The patient was the subject of exophthalmic goitre, and she had been operated on by resection of the sympathetic. The results were as follows: first, a most important diminution of the exophthalmos; secondly, lowering of the heart beats from 200 to 100 in the course of a week, while at the same time the painful pulsation in the precordium disappeared; and thirdly, there was no marked effect on the goitre itself. Messrs. Combemate and Gaudier concluded from their observations that in cases of exophthalmic goitre, when the tachycardia is intense and continuous, when this is the only symptom, or when there is also exophthalmos, there is always the risk of dangerous symptoms supervening. In such cases section of the cervical sympathetic, which acts most probably by preventing the hypersecretion of the thyroid gland, is the best operation to do.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 6, 1898.

THE SUPRATONSILLAR FOSSA AS THE STARTING-POINT OF INFECTION.

THE function of the tonsils has always been one of the disputed questions of the physiology of the pharynx. That they are normal avenues of absorption was at first believed and then disbelieved. We no longer credit them with a share in blood formation, "nurseries for the young leucocytes planted by the waterside and drawing their sustenance from the streams nutrient." Nor can the doctrine of phagocytosis be regarded as positively proven so far as concerns its application to this special structure.

Some recent experiments by Goodale, of Boston, would seem to establish four definite conclusions, namely: 1. Absorption exists normally in the tonsil and takes place through the mucous membrane of the crypts. 2. The path of absorbed substances in the tonsil is in the interfollicular lymph spaces in the direction of the larger fibrous trabeculæ. 3. During the process of absorption foreign substances encounter phagocytic action on the part of the polynuclear neutrophiles, situated in and adjoining the mucous membrane. 4. Bacteria are normally present in the crypts, but are not, at least ordinarily, demonstrable in the tonsillar tissue. It is a satisfaction to have demonstrated what provides a simple and logical explanation of many of the clinical problems of sore throats. It is a matter of common occurrence that many cases of contagious disease seem to originate through throat infection, and the proper care of the tonsils cannot therefore be overestimated.

In a recent paper by Dr. Paterson, of Cardiff, England (*Laryngoscope*, July, 1898), an effort has been made to set forth the practical side of the question and to determine just what part of the tonsil is the outpost so often carried by the invading enemy. We now know that many cases of throat disease which are bacteriologically distinct are identical from a pathological point of view. Paterson calls special attention to the supratonsillar fossa, an anatomical space which is occasionally to be found just above the tonsil between the pillars of the fauces at the apex of the interstitium. In the development of the parts about the pharynx we have the arcus palato-glossus, formed from the second visceral arch. The palate, growing as a fold from the upper jaw, crosses this arch, as well as the corresponding second cleft, and divides it into an upper and a lower part. The remains of the cleft above the palate form the fossa of Rosenmüller; below the palate lymphoid tissue develops, forming the tonsil and the remainder of the cleft at the upper part constituting the supratonsillar fossa. This space is therefore the remains of the second visceral cleft. That part of the tonsil which presents toward the fossa has an arrangement of structure which differs somewhat from that of the rest of the organ, and this is a point of great practical importance. The lymphoid tissue is in the form of a very loose, open network, much less compact than the lower part of the gland. Above it is spread out along the walls of the space in processes like fingers and toes, or like miniature columnæ carneæ and musculi papillares. The lacunæ freely communicate with each other and are themselves of large size. As they pass down into the substance of the tonsil they narrow, while some run downward to open by small mouths on the surface of the organ. Hence the products from the upper follicles tend to find an outlet in the fossa rather than on the surface of the tonsil.

The consequence of this peculiar anatomical arrangement is that the fossa is frequently blockaded by plugs, which become aggregated into cheesy matter, readily decomposing and becoming very offensive. They set up irritation, and, if not artificially removed, may lead to the formation of tonsilloliths.

Careful dissection frequently shows that the smooth wall of the fossa, composed of mucous membrane, is reflected on to the deep muscular tissue and areolar structures. It may come in contact with the superior constrictor of the pharynx. This explains the fact that these structures are not infrequently involved in the common "quinsy" sore throats. The fossa often extends a variable distance into the soft palate. The "chronic abscess of the soft palate," about which much has recently been written, is doubtless nothing but an occluded supratonsillar fossa, the contents of which have become purulent, as regularly happens whenever the outlet to a mucous cavity becomes stopped up. When the pharynx is in a normal condition, the cavity of the fossa is freely open to the buccal cavity. There is no accumulation of secretion and hence no irritation. Under the opposite conditions plugs form of epithelium, leucocytes, mucus, lime salts, and bacteria.

Through the fossa doubtless enters the tubercle bacillus, setting up a cervical adenitis, which is without any question the most frequent cause of enlarged glands in the neck. A thorough curettage of the fossa is often followed by subsidence of these enlargements. Mere removal of a portion of the tonsil with the guillotine does not effect the same result, unless by this procedure the cavity of the fossa is freely laid open. The operation of tonsillotomy, as generally performed, often fails to reach the top of the gland, and unless this is removed the radical cause of many throat inflammations escapes notice.

THE STAMPING OUT OF YELLOW FEVER IN CUBA.

If the only outcome of the present war were the disappearance of yellow fever from Cuba and the cleansing of the pestilential port of Havana, this country would not have fought in vain. That Havana in its existing unsanitary condition is a menace to every neighboring people and State, is an assertion that can be made without fear of contradiction. That both the town and harbor by the application of a little engineering skill can be rendered as healthy as any in the South, is, in the opinion of experts, quite practicable; but that any steps tending in this direction will be taken under Spanish rule is just as surely not to be looked for. Therefore the sooner this rule ceases in Cuba the better it will be for the public health of America and of the world at large. If proof were needed that yellow fever is essentially a disease which flourishes amid filthy surroundings, and that when these favoring conditions are removed abates and in some instances wholly disappears, we might cite Jamaica, Mexico, and the Danish West Indian islands as examples of the good results following proper sanitary measures. Indeed, north of the equator Havana stands as almost the sole and certainly as the chief source of this particular form of danger to the commercial nations of the world. From its proximity to Cuba, this country has been the principal sufferer from Spanish neglect of the laws of health, and undoubtedly whatever form of government may be decided upon for Cuba, the authorities at Washington will insist that the unsanitary conditions now prevailing at Havana shall no longer continue. Many suggestions have already been made regarding the sanitation of Havana, and it is claimed by those experienced in such matters that there are no difficulties in the path which cannot easily be overcome by American ingenuity and perseverance. The geographical configuration of Cuba, with hills of a considerable height at a short distance from the coast, lends itself to an efficient system of drainage.

Dr. George Homan, of St. Louis, read before the Medical Society of the Hospital Alumni of that city, on May 5th of this year, a paper entitled "The Sanitary Redemption of Havana," in which the need of reform is eloquently pointed out, as also the means whereby the desired end may be reached. He says: "Yellow fever, being essentially a disease of sea level, thriving best in combined moisture, filth, and heat, clinging especially to the foreshore, wharves, docks, ship holds, etc., Havana presents special conditions for its growth and harboring, and therefore requires special means for its eradication. This implies one or two things: to wit, either that some method shall be found by means of which the waters of the bay will be regularly and frequently changed, or else that the pollution now poured into it shall be diverted and safely disposed of elsewhere. . . . To effect the former, it has been proposed to cut a canal leading from the bay to a point on the north coast, with a view to establishing a current toward the Gulf. . . . The other alternative is the diversion of the sewage now delivered into the bay and its disposal elsewhere without prejudice to public health. This would involve the construction of an intercepting sewer along the water front to receive the outfall of drains carrying domestic and manufacturing waste, and is a measure so commonly resorted to that no novelty presents itself in connection with the suggestion."

Whichever method is adopted, provided that it is effectual, matters little, but that the present Spanish "let-things-slide" way of management is intolerable and should no longer be permitted to continue is the opinion of all civilized peoples. However, a radical change will soon be made, and we have every reason to believe that yellow fever will be driven from its last stronghold; in fact, it may not be rash to predict that, if the Brazilian sanitarians can be awakened to their duty, many of those now living will see the day when yellow fever will have been stamped out and mankind delivered from one of the most deadly of the tropical scourges.

PRACTISING ABORTION FOR A LIVING.

The case of Dr. Collins, who has recently been sentenced in England to a term of seven years' penal servitude for performing an illegal operation upon a woman which resulted in her death, has once again attracted attention in that country to this too frequent form of crime. The *Times*, commenting on the prevalence of abortion among the women of the upper classes in England, says that these cases throw a lurid light upon some of the consequences of modern luxury and upon some of the standards of morality which are accepted in certain circles of modern life. These words, we fear, will apply with equal force to the upper classes of America. With regard to Great Britain, and especially London, it has been for long a matter of common knowledge that there are medical men who are willing for the sake of gain commensurate with the risks they run to commit the crime of fœtal murder. The men who thus prostitute their abilities are either those who, like Collins, have lost their reputation and are unable to practise their profession in a legitimate manner, or those who are driven to these evil ways by the stress of poverty. But although their conduct is of course indefensible, it must be said that much of the blame rests with the women themselves, who, determined not to undertake the duties of maternity, tempt weak-minded medical men by large offers of money to commit this detestable crime. The judge, when summing up in the Collins trial, took occasion to say that "the woman who submits herself to an unlawful operation is guilty of felony just as much as the agent she employs," and it might go far to prevent the murder of the unborn were this aspect of the case more dwelt upon. The fear of disgrace and punishment in this world often acts as a more efficient deterrent from crime than does any dread of consequences in the hereafter.

Illness of Liliuokalani.—It is reported that ex-Queen Liliuokalani, of the Sandwich Islands, who recently returned to Honolulu, is suffering from a malignant growth in the neck.

CHEMICAL AND UROTOXIC INVESTIGATIONS OF FATIGUE IN THE HUMAN SUBJECT.

During the six-day bicycle race which took place in New York City some few months ago, Dr. Bookman availed himself of the opportunity thereby afforded to investigate extreme muscular, nervous, and mental fatigue, from the chemical as well as from the urotoxic point of view (*State Hospitals Bulletin*). As may be believed, the race in question afforded an excellent occasion for making such investigations, and the conclusions arrived at should prove of much practical value. When it is stated that during the six days of racing the subject selected for the observation was off his wheel less than half a day, and that he slept a little less than five hours in that time, it will be seen that the selection was a wise one. From a careful examination of the urine, Dr. Bookman made the following deductions: That the metabolism was greatly reduced in its production of sodium chloride, uric acid, phosphates and urea, total solids and water. This is explained as due to the perspiration, carrying off the phosphoric acid and possibly conveying with it sodium chloride and water, in addition to small amounts of urea and solids which might have been also secreted in the perspiration, thus robbing the urine of its normal amount of these constituents. The small amount of uric acid found is accounted for thus: As there is no possibility in cases of extreme muscular exertion for the metabolism to possess a low oxidizing power, it is self-evident that the uric acid, which is a less highly oxidized product than urea, cannot remain in that state, it will therefore be completely oxidized to urea. Dr. Bookman then proceeds to say:

"It will therefore be seen that the metabolism has not been impaired whatsoever in this case, the variations in the amounts of the few constituents mentioned being easily explained by natural processes occurring in the body of the person engaged in this exercise. We may thus infer that no injury has been done to any organ, since this would have manifested itself in our investigations."

Further proof is, however, afforded on this point by a series of experiments on rabbits, made by Dr. Bookman, which showed beyond doubt that the urine of man examined exhibited a lower toxicity than that of the normal subject. Finally, Dr. Bookman inquires: "Does the overexertion in cases like this produce any effect which may be deleterious to the human system, and can the body, by careful training, not accustom itself to this, regarded by many as an almost superhuman performance?"

Busy Doctors.—Two healers of men, each yearning for good works, met on the highway of a great city, and one forthwith said unto the other, "Art thou busy?" Whereupon he that was accosted replied, "Yea, verily." The father of lies, who was likewise passing that way, smiled and said thus unto himself, "Even so with me," and readily joined himself to each of them; and all went their way together.

THE MEDICAL DEPARTMENT OF THE ARMY.

We are pleased to give the surgeon-general and Colonel Senn the amplest opportunity for direct explanation. The facts so authentically stated by them on pages 213 to 215 of this issue will doubtless tend to place the medical department of the army in its proper light before the profession and the public. Our sole purpose in writing the editorial was to get at the bottom of the numerous charges of neglect of the sick and wounded by inviting an official answer to our query. So far we have succeeded in our purpose. We are most happy to learn from them that at least the medical department of the army is not to blame for any dereliction of duty or lack of preparation for emergency. We are always willing to hear both sides of any question, our only object being to get at the truth. Every incentive for discussion is perfectly legitimate when such an end is in view. For the present and in the same spirit, we are willing to rest the question, pending the possibility of future developments bearing on the point at issue.

News of the Week.

The British Medical Association held its sixty-sixth annual meeting last week in Edinburgh. In another column will be found full abstracts of the addresses delivered in the general sessions. These we are enabled, through the courtesy of the editor of the *British Medical Journal*, to present to our readers in advance of the special report which has been made by our own correspondents and which is now on the way.

An Invalid's Dietary.—When the cable first announced that Prince Bismarck was very seriously ill, it was stated, in confirmation of the report, that his diet for that day consisted of ham, caviare, eggs, beer, and champagne, but that he had foregone his favorite pickled pigs' feet.

Drs. Bowditch, Osler, and Roddick Honored.—The University of Edinburgh, on July 30th, conferred the honorary degree of doctor of laws on a number of men who had been in attendance at the meeting of the British Medical Association, among whom were Drs. Henry P. Bowditch, of Boston; William Osler, of Baltimore; and Roddick, of Montreal. The last named was president of the association at its meeting in Montreal last summer.

The St. Patrick's Insane Asylum, in Dublin, which was founded in 1750 with a bequest of £12,000 by Dean Swift for the benefit of the imbecile and insane, has just acquired a mansion surrounded by two hundred acres of beautiful grounds at the suburb of Lucan, and this is to be used as a convalescent home for the asylum for the benefit of those patients who are likely to profit by change of air and scene. This is the first time such a step has been taken in connection with an Irish insane asylum.—*The Hospital.*

Three Views of the American Medical Editors' Association.—The meeting was remarkably well attended, and a vein of unusual seriousness regarding

the ethics of advertising was exhibited. The expression of this took the form of the following resolution, which was unanimously adopted:

"*Resolved*, That matter which, in the judgment of the editor, is clearly in the nature of an advertisement or reading-notice shall be excluded from the regularly paged parts of the journal and placed exclusively in the advertising pages."

Upon adjournment the members and their guests repaired to the banquet hall, where plates were laid for one hundred and fifty.—*Nashville Journal of Medicine and Surgery.*

In connection with the meetings of the American Medical Association there are a number of other medical societies that hold their meetings at the same place, and nearly at the same time, for the convenience of the members who belong to two or more of the organizations. Among these are the American Medical Editors' Association, the literary, scientific, and journalistic virtues of which seem to be satisfied with a banquet. At the meeting this year a slight spasmodic quiver of intellectual life was momentarily shown in a resolution to exclude reading-notices and advertisements from the reading-columns, but exhaustion and collapse immediately followed when it was also proposed to exclude from the advertisement columns advertisements of secret remedies and those appealing directly to the lay public. This brought a ludicrously hasty supply of the undebatable motion to adjourn.—*Philadelphia Medical Journal.*

This association did not accomplish very much at this meeting outside of enjoying a first-class banquet. Certain steps were taken which we believe will, however, make this association a power in the land. A committee on revision of the constitution and bylaws was appointed by the incoming president. This committee consists of Dr. I. N. Love, St. Louis; Dr. Dillon Brown, New Jersey; Dr. Joseph Mathews, Louisville; Dr. Henry B. Coe, Portland, Ore.; and Dr. George Simmons, Lincoln, Neb. This committee will not only draw up a revision of the constitution and bylaws, but it will frame a platform which, when adopted, will be presented and will be in the hands of every medical editor in the United States. It will tell the relation of the editor to the advertiser and of one editor with another editor. . . . A resolution at this meeting was passed derogatory to the publication of reading-notices. The officers of the association for the ensuing year are: Dr. Thomas H. Hawkins, Denver, *President;* Dr. George Simmons, Lincoln, Neb., *Vice-President.—Denver Medical Times.*

The Gorgeous Toggery of an F.R.C.S. — It is announced that the new gown to be worn by fellows of the Royal College of Surgeons on ceremonial occasions will be of black stuff with crimson satin facings of a regulation shape and shade. Fellows who are graduates of any university may wear, instead of the fellow's gown, the gowns representing their degrees, provided they are more attractive in appearance than the former. The democratic simplicity of the proposed button of the American Medical Association is in marked contrast to these variegated garments, and yet there are some modest members of the A. M. A. who object to being labelled even by a button.

German Commercialism.—Another illustration of the degradation of German science, which has been so conspicuous in the open alliances between Koch and other bacteriologists and the manufacturing chemists, is furnished by the attempts of Behring to establish a monopoly in diphtheria antitoxin. After many failures he has at last secured a patent on the manufacture of this remedy in the United States, and now thinks he is in position, with loaded syringe, to demand of every defenceless babe its money or its life. We do not believe the courts will legalize any such impudent attempt at brigandage.

Fears for Antarctic Explorers.—It is reported from Antwerp that the gravest fears are entertained there for the safety of the steamer *Belgica*, which sailed on August 15, 1897, bound for Graham Land with the Antarctic expedition on board. It is feared that the ship has been lost or is locked up in the fields of ice. Dr. F. A. Cook, of Brooklyn, is the surgeon and ethnologist of the expedition.

A Light Weight.—A baby was born in a Newark hospital recently, whose weight at birth was forty ounces. The father and mother are Italians, aged respectively seventeen and sixteen years.

Death from Nostalgia.—A dispatch to the adjutant-general of the army from Santiago recently stated that a private in one of the Massachusetts regiments had died of homesickness.

A Supply Boat for the National Relief Commission.—Mr. A. Van Rensselaer has placed his yacht *May* at the disposal of the National Relief Commission of Philadelphia, for use as a supply ship. The yacht was intended to sail this week, having on board Messrs. William Potter, Alexander Van Rensselaer, and Dr. George G. Groff, president of the Pennsylvania State board of health, as special commissioners representing the National Relief Commission at Porto Rico. They will establish a depot for the reception of supplies at Porto Rico. The *May* will carry an apparatus for manufacturing ice, which is to be used at the Relief Commission's storehouse in Porto Rico. An ice plant will also be sent to Santiago, which will be capable of manufacturing all the ice that is needed by the division hospitals at that port. This ice plant has been presented to the Relief Commission by a citizen of New York.

Dr. N. S. Davis has resigned the office of dean of the Northwestern University Medical School (Chicago Medical College), with which he has been connected since its foundation, and of which he has been executive officer since 1865.

Papers Read at the Meeting of the American Medical Association.—The contributions before the American Medical Association at the Denver meeting include a total of 711 papers, divided as follows: Practice of medicine, 45; surgery and anatomy, 71; obstetrics and diseases of women, 57; ophthalmology,

56; laryngology and otology, 38; diseases of children, 62; materia medica, 81: physiology and dietetics, 43; neurology and medical jurisprudence, 89; cutaneous surgery, 24; state medicine, 33; stomatology, 16.—*Medical Sentinel.*

The British Ophthalmological Society.—At the meeting of this society, held on July 8th, the following officers were elected: *President*, H. R. Swanzy; *Vice-Presidents*, Sir W. R. Gowers, Drs. Argyll Robertson, R. Marcus Gunn, R. Williams, E. Nettleship, Henry Eales, W. A. Brailey, Priestley Smith, F. R. Cross, and George Cowell; *Treasurer*, Dr. John Abercrombie; *Secretaries*, Dr. James Taylor and E. Treacher Collins; *Librarian*, W. Adams Frost.

Gift of a Hospital Ship.—The use of the steamship *Missouri*, now being converted into a hospital, together with the services of her crew and all the coal she may consume, has been given to the government without charge for as long a time as she may be needed, by the Atlantic Transport Line, of Baltimore, through Mr. B. N. Baker, the president of the company.

Camp Alger.—The typhoid fever at Camp Alger, Va., may fairly be said to be epidemic. The number of new cases reported has been nearly fifty a day, and any doubts as to the contamination of the water supply are now dissipated. Surgeon-General Sternberg has urged upon the secretary of war the necessity of withdrawing all the troops from the camp, the medical officers who have any knowledge of the conditions prevailing there being unanimous in their recommendations to abandon the present site.

The Sultan's Opinion of London Surgeons is apparently not what it should be, for it is said that when he telegraphed his condolences at the time of the accident to the Prince of Wales, he offered as a special demonstration of his solicitude to send the Turkish surgeon, Djemal Pasha, to attend the prince.

A New Camp at Montauk Point.—Surgeon-General Sternberg has reported to Secretary Alger favorably on the selection of Montauk Point, at the eastern extremity of Long Island, as an encampment for the troops under General Shafter in Santiago. The report says that the locality is healthful, cooled by breezes from the ocean, and ample in area for the purpose; it has a fine port and is easily supplied with good water.

The Sanitary Condition at Santiago at the time of the city's surrender was about as bad as could be imagined. The city has always been, at its best, a fair sample of Spanish unsanitation, but after a two-months' siege it was filthy beyond description. Heaps of ordure and decaying animal and vegetable refuse were everywhere, and the stench arising from them was enough to turn the Northern stomach. There is no sewerage system. The city drainage is all from the surface into the harbor, and the lower part of the city, through which much of the drainage runs, especially from the poor quarter around the bull ring, to the northwest of the city, is the seeding-centre of malarial, typhoid, and other low fevers. There are four hospitals in the city—the Civil Hospital, presided over by the sisters of charity; and the Military, Mercedes, and Conchas hospitals. In these four hospitals were 1,747 patients. When the notification of the proposed bombardment was received, every patient who could stagger out was driven into the streets. Among them were twenty lepers, who were in the Civil Hospital, and they are said to be still at large.

A Field Hospital at Montauk Point.—A medical officer has been sent from Washington to establish a field hospital, with accommodations for five hundred patients, at Montauk Point, which has been selected by Surg.-Gen. George M. Sternberg as the site of the camp for General Shafter's fifth army corps as soon as circumstances admit of its being brought North.

"The Woman's Medical Journal."—Mrs. Margaret L. Hackedorn writes us that the only change that has been made in the editorial staff of this journal is that the writer succeeds Mrs. Murphy as managing editor, the other editors continuing under the new management. The policy and general make-up of the paper will remain unchanged.

The American Electro-Therapeutic Association.—The eighth annual meeting of this association will be held in the Library Building, Lafayette Square, Buffalo, on September 13, 14, and 15, 1898, under the presidency of Dr. Charles R. Dickson. In addition to a large number of papers there will be a series of ten-minute discussions on electro-therapy, including effect of electricity on tissue metabolism, electro-diagnosis, diseases of the nervous system, diseases of women, genito-urinary diseases, malignant growths, orthopædic uses, diseases of the eye, etc. Among the entertainments provided there will be tally-ho coach drives about the city daily, a public reception on Tuesday night, an excursion down the Niagara River, and a reception at the Island Club, Grand Island. An excursion train for the accommodation of members and their families will leave New York on Monday morning, September 12th. Information concerning tickets, etc., may be obtained from Dr. Robert Newman, 64 West Thirty-sixth Street. The secretary of the association is Dr. John Gerin, 68 North Street, Auburn, N. Y.

Attempt on the Life of a Physician.—Dr. E. D. Skinner, of Mineola, Long Island, one of the coroners of Queens County, was shot in his own house, a few days ago, by an unknown assailant. Although the wound was a very serious one, the patient is doing well and his recovery is hoped for. Dr. Skinner was born in Greenport, Long Island, in 1838, and was graduated from the Berkshire Medical School in Pittsfield, Mass., in 1858. He was for a number of years health officer of the town of Hempstead, and was elected coroner in November, 1896. He is ex-president of the Queens County Medical Association.

The Yellow Fever at Santiago still continues in mild form, as far as can be learned from the meagre reports sent by the sanitary authorities. The number of "fever cases" is reported as between three and four thousand, but most of them are of typhoid and malarial fevers. The deaths from all causes in the army numbered fifteen on August 1st.

A Silly Performance.—On Monday last a woman left New York at midnight on a bicycle, and reached Boston at three-quarters of a minute before midnight, lowering the previous record of twenty-four hours four minutes by four and three-quarters minutes. How much she reduced her allotted span of life by this senseless feat it is impossible to say, but it was doubtless several times as many years as minutes by which she lowered the record.

Arrest of a Prescribing Druggist.—A druggist was recently arrested and held in $100 bonds for trial in special sessions, on a charge of violating the law forbidding druggists prescribing for patients. Two women agents of the Medical Society of the County of New York testified that the prisoner had prescribed for them, charging $2.15 for advice and medicine. The druggist pleaded that he only sold the women patent medicines, but the magistrate said that he had no right to prescribe, his business being merely to fill out prescriptions, and he was therefore held for trial.

Obituary Notes.—Dr. Charles S. Ward, of Bridgeport, Conn., died in that city on July 31st, at the age of fifty-five years. He retired from active practice some years before his death. He was a Yale graduate and a member of the Yale Alumni Association, the University Club, Society of Colonial Wars, and St. Nicholas Society of this city, and the Quinnipiac Club and the Graduates' Club of New Haven.—Dr. George C. Hubbard, assistant sanitary superintendent for the borough of Richmond, died suddenly at his home in Tottenville on August 3d. He was for nearly forty years one of the leading practising physicians in Richmond County. Dr. Hubbard was born in Ohio in 1831, and was a graduate in medicine of the University of the City of New York in the class of 1859. He was a veteran of the civil war, having served as assistant surgeon of the one hundred and sixty-fifth New York volunteers. After the war he returned to Tottenville and resumed his practice. He was physician to the Mount Loretto Home at Pleasant Plains. Dr. Hubbard leaves a widow and two sons.

Obituary.

WILLIAM PEPPER, M.D., LL.D.,

PHILADELPHIA.

Dr. William Pepper died suddenly on July 28th, of heart trouble, near Pleasanton, Cal., where he was passing a few weeks on a ranch to recuperate after a winter of more than usually arduous labor. Dr. Pepper, son of a physician of the same name who died in 1864, was born in Philadelphia, August 21, 1843, and was therefore within three weeks and three days of fifty-five years of age. He was a graduate in arts of the University of Pennsylvania in the class of 1862, and in medicine in the class of 1864. Endowed with great talent, supported by a genius for application, and aided by influential family and professional relations, he soon became recognized at home and abroad as one of the leaders of medicine in his native city. In 1866 he became curator and pathologist to the Pennsylvania Hospital, where he had served a term as interne, and the following year was appointed visiting physician and pathologist to the Philadelphia Hospital. In 1868 he first became officially connected as a teacher with the University of Pennsylvania, which owes in such large measure to him the high rank which it now holds among the universities of the country. In that year he was appointed lecturer on morbid anatomy; in 1870, lecturer on clinical medicine; in 1876, professor of clinical medicine; and in 1887, professor of the theory and practice of medicine.

In 1881 Dr. Pepper was elected provost of the University of Pennsylvania, and continued to discharge the onerous duties of that office, in addition to his labors as a teacher and practitioner of medicine, for thirteen years. When he assumed the burden of provost the university had 88 instructors and 981 students; when he retired from the provostship there were 268 instructors and 2,180 students on its rolls. The amount of land owned by the university increased during his term of office from fifteen to fifty-two acres, and its lands, buildings, and endowments grew in value from $1,600,000 to more than $5,000,000. One of the first and most notable additions to the university under Dr. Pepper's administration was the Wharton school of finance and economy. Then came the department of philosophy for postgraduates. The department of veterinary medicine was added in 1883, the school of biology and the department of physical culture in 1884, and the school of American history and the department of archæology and palæontology in 1891.

Among the additions under his régime were the biological laboratory, the school of hygiene, and an admirably equipped library building. This was erected in 1889, and about the same time the dental department came into prominence. His most important work, however, in the development of the university, was undoubtedly that accomplished in the direction of higher medical education. This advance was secured through the extension of the course of study to four years.

Upon his retirement from the provostship in 1894 he presented the university with a gift of $50,000.

Dr. Pepper took a prominent part also in public life. He was largely instrumental in founding the Pennsylvania Museum and School of Industrial Art, and was for several years a member of its board of managers. In 1882 he was a member of the assay commission of the United States mint. He was president of the first sanitary convention of Pennsylvania, and of the Foulke and Long Institute for orphan girls. He took a large part also in the organization of the Philadelphia Commercial Museum and was president of its board of trustees. He was recently mentioned quite prominently as a probable nominee for mayor of Philadelphia.

Dr. Pepper was widely known as a medical writer of great ability. He was the founder and first editor of the *Philadelphia Medical Times*, and edited two systems of medicine, besides being a frequent contributor of papers on various subjects to the medical press. He was medical director of the Centennial International Exposition in 1876, and for his services in connection therewith he received from the King of Sweden the decoration of knight commander of the Order of St. Olaf. He was president of the first Pan-American Medical Congress in Washington in 1893, and was one of the orators at the second congress in Mexico in 1896. He was a fellow of the College of Physicians of Philadelphia, a member of the American Philosophical Society, of the Pathological Society of Philadelphia, of which he was president in 1874-76; of the Academy of Natural Sciences, of the American Medical Association, of the Association of American Physicians, of the American Climatological Association, of which he was president in 1886; and of many other scientific bodies.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-Sixth Annual Meeting, Held in Edinburgh, July 26, 27, 28, and 29, 1898.

ADDRESSES IN THE GENERAL SESSIONS.

Mutual Obligations of the Profession and the Community.—Sir T. Grainger Stewart, of Edinburgh, delivered this, the president's address. He began with a welcome to the city, an ancient and famous seat of medical learning, and with an expression of thanks to the association for having called him to occupy a position which had been filled by Alison, by Christison, by Stokes, by Acland, and by many other illustrious men. He then adverted to the losses which the association had sustained in the deaths of many distinguished members, and especially of Mr. Ernest Hart, who during many years edited the *British Medical Journal* and took a leading part in the conduct of the association. No subject, he said, could more worthily form the topic of an address on an occasion like this than a consideration of the reciprocal duties of our profession to the community and of the community to our profession. The respective duties may be described in a single sentence. That of our profession is to do its best to prevent disease, to cure disease, and to alleviate suffering in individual patients; to protect the community against preventable maladies; to advance our knowledge; to train our successors, and to guard the portals of admission to our ranks. The duty of the community is to afford us every facility for so doing.

He purposed to speak briefly of each of these, and then to refer to the various organizations instituted by the profession and the community with a view to the fulfilment of their respective duties.

It is, to begin with, most desirable that a common understanding should exist as to the present position of the science and art of medicine. The days are past in which medical men were accustomed to make great claims as to their powers, arrogantly pretending to control processes of nature which we are really unable materially to influence. Our profession recognizes its limitations; none know so well as we how imperfect our art still is, and how little it can achieve compared with what we would desire. Still we know that medicine has advanced amazingly during the present century, and is advancing every day in all directions at an accelerated and ever accelerating speed. The annual death rate in England and Scotland has since 1855 fallen by more than one-fifth. The proportion of deaths from zymotic diseases as compared with other causes has diminished by more than one-third; the labors of members of our profession have mainly brought about these results. Even the great scourge of humanity, tuberculous disease, has been robbed of some of its terrors. The mortality due to it has fallen by one-third during the past thirty years. Our rapidly advancing knowledge is supplying us day by day with new precautionary measures which are certain further to diminish the frequency of the disease and its rate of mortality. The public takes cognizance of facts like these, and is therefore according year by year a higher measure of respect to our art, imperfect though we must acknowledge it still to be.

Individual Doctors and Individual Patients.—There is little need to enlarge upon the personal relationships of doctors and patients. The duties which the practitioner owes are universally recognized. He has to master the art of medicine to the best of his ability and then to apply his knowledge for the benefit of each individual who may come under his care. If we can claim that our duty is fairly performed at the present day, it is equally true that the public shows a generous appreciation of the services of individual doctors. It fully recognizes our honest good intent, and if it sometimes evinces less gratitude than we know or think we deserve, on the other hand it often accords us more; and if we treat our patients from the humblest to the highest with care, courtesy, and discretion, it will be found that, generally speaking, we have not to complain of any want of appreciation and gratitude.

The Profession and the Legislature in the Prevention of Disease.—The prevention of disease is in its practical results perhaps the most important of all our duties. It is our chief glory that we have been able to accomplish so much. It is our highest hope that we shall accomplish more.

The great group of diseases which owe their origin to invasion by pathogenic micro-organisms is in course of being rationally explained, and so it is becoming possible for us to take measures for their prevention. In some of them we can prevent the development of the organisms. In some we may hinder their multiplication and spread. In some we can block the channels by which they have been accustomed to find entrance into the body. In some we are able to modify the germ so that it produces when inoculated a milder disease, and yet a disease capable of conferring immunity against the malady in its ordinary form. In some we can interfere with the action of the germ even after it has been introduced, or counteract the poisonous substances which the germs generate. With regard also to the important group of diseases due to faulty chemical processes, we have learned much that is of service for prevention. Each discovery which renders causation of disease more clear contributes something toward its prevention.

Every member of the profession ought to be keeping his eyes open to the advances of science, always seeking for an explanation of the occurrence of disease, and especially of epidemic outbreaks, for by watchfulness in such matters mighty results can be achieved. The public may in many ways benefit from such discoveries and the precautions they suggest. Individual health, family health, social health, and national health may all be improved if the individual, the head of the family, the employer of labor, and the legislator duly study and act upon these lessons. But an intelligent appreciation of these subjects is not easily attained. Perhaps we are ourselves in some measure to blame for this, because our professional customs do not readily lend themselves to the issuing of clear and popular statements by leaders of medical opinion, in such forms as would enable the public to share our knowledge. We ought to take more pains to instruct the public in such questions.

In unnumbered ways may intelligent and well-instructed men ward off dangers by attending to the hygienic rules of modern science. But, apart from all the private applications of hygienic laws, rises the question of the duty which the legislature owes to the facts of medicine. Now when every man is a king, when the whole people rules, it is perhaps not so easy to attain the results that we desire. The whole community must to instructed before the lessons can be used to good purpose. It is our task to give that instruction; it is that of the community to give effect to what we have taught.

With regard to the question of penalties for violation of health laws, many suggestions have been made, but there is a more excellent way. By steady perseverance in the instruction of the people, and showing them the effects of the improved legislation, and getting them rightly to understand the question in all its bearings on themselves and their children, they will

become so convinced that they will not only avail themselves of the offered protection, but will demand wider and more effective legislation. The legislature should boldly accept the principle that, as it is mainly guided by the opinion of lawyers as to legal questions, by those of soldiers in matters military, by practical seamen and engineers in matters concerning their department, so in medical questions they should look for guidance to the medical profession, and give effect to its matured opinion.

The Acquisition and Extension of Knowledge.—Another duty recognized from earliest days is that of extending, increasing, and deepening our knowledge. The *mens medica* is an inquiring mind, and the nature of our training and of the problems which daily confront us stimulates inquiry. Original observation and research are being carried out in unnumbered centres throughout the world. The mediæval methods of building systems or theories upon slight or fanciful foundations have been replaced by the Baconian methods. To these the world is indebted for boundless benefits. Every great hospital has been for long used as a field of accurate and painstaking clinical observation, and in many of them and in every university and school laboratories of research have been established and original work has been incessant. It is much to be desired that the community were more appreciative of the value and importance of such work, that there were less of ignorance regarding the results, and less prejudiced opposition to the methods employed; but in this respect also, as the fruits become apparent, the value of the work is being admitted, and confidence and respect are deepening.

The Training of our Successors.—From the earliest days the instruction of future physicians has been recognized as one of our most important functions. At first it seems to have been accomplished by transmission from father to son or from master to disciple. Just as one sees in the present day among the Savoyards at Aix-les-Bains the fathers training their sons and the mothers training their daughters in their traditional methods of treatment, so the old-world physician handed on his knowledge. By degrees the training came to be intrusted to individuals specially set aside for the work, and teaching was gradually organized.

After touching briefly upon the history of medical education in Great Britain during the past three centuries, the speaker said that to-day the profession has organized throughout the country many great and famous medical schools, and all the universities devote themselves more or less to medical education. That work, of course, can never be successfully accomplished except where great hospitals exist.

He expressed the wish that all teachers could manage to make their instruction a training of the powers and mastering of the methods, rather than a loading of the memory with unnecessary facts and transient theories; and also that it were possible for the universities and schools to make more complete and satisfactory arrangements for post-graduate instruction, so that old students might return to the alma mater and pick up in the course of a few weeks instruction as to new methods and new facts whereby they might keep themselves more abreast of modern progress.

Medical and State Medical Organizations.—Under this heading Sir T. Grainger Stewart dwelt especially upon the growth and the objects of the British Medical Association, an organization which had fully justified its existence by the great good it had accomplished. He also referred briefly to the General Medical Council, which he thought had done good service to the profession and the state in the forty years since it had been created.

The Public Health Executive.—By this term the speaker meant all the officials who are intrusted with carrying out the laws relating to disease and its prevention. The formation of the department was—like most British institutions—an evolution rather than a creation; for when the government felt the need of establishing such a branch of the executive, it did not construct a new board or appoint new officers, more than was absolutely necessary, but rather laid additional duties upon boards and officials already existing.

He thought that the duties of the local government board might be simplified with much advantage. The department had grown so great and so complicated, and the importance of the work of some of its parts had become so much more appreciated, that it demanded reconstruction. The local government board should be intrusted with every question that bears upon public health. It should have two divisions—one dealing with the questions of local administration, and the other with the public health. The president of the board should be recognized as an official of the higher rank, and should indeed be not only a minister, but a secretary of state for the department. It would be a great benefit that he should be an officer of such dignity and influence that he would be able to secure in the cabinet and in Parliament due attention to the subjects with which he has to deal.

An Illustration of Mutual Duties Well Fulfilled.—In closing his address, the speaker presented an illustration of what he conceived to be the ideal working out of the mutual duties of a medical officer and of the department to which he stands related. "My friend Dr. Aitchison had in the discharge of his duties observed that the inmates in St. Cuthbert's Poorhouse were throwing out nitrogenous matter from the system in a proportion far beyond that which they were taking in by way of food. The nitrogenous waste was so great that the paupers might have been described as in a state of 'physiological bankruptcy.' In well-fed healthy individuals the store of glycogen within the organism is kept at a level which amply suffices to meet the requirements of the system, and even if on any occasion the daily supply falls short there is the fat stored within the body, which can easily be drawn upon as occasion requires. But beyond these are the nitrogenous tissues which are brought into use only when the other two sources of supply are exhausted, and are so used at great expense to the organism. Dr. Aitchison found that our paupers were not fed in such a way as to meet the daily expenditure; that whatever stores of fat they might at one time have had were completely exhausted before they had long been living upon the poorhouse fare, and that consequently they were obliged to fall back upon their nitrogenous tissues, to the great diminution of their energy and strength. Their output of nitrogen, instead of being a normal of, say, fifteen to twenty grains, was from thirty to forty grains *per diem*. He soon ascertained that this nitrogenous waste went on all the same, whether the food supply of nitrogenous material was given in proper quantity or deficiently or in excess. And by degrees he satisfied himself that the fault lay in the deficient supply of the fatty materials. He therefore provided for certain paupers an additional allowance of fatty materials in the form of suet pudding, and found the nitrogenous waste greatly diminished. He then was able to determine the amount of fat required, by noticing when in each case he got the nitrogen equilibrium established. These results were presented to the university in the form of a graduation thesis for the doctor's degree, and Dr. Aitchison received the degree with the highest honors. He then placed the work in the hands of the local government board. The board after consideration and conference sent the diets which he suggested to every poorhouse

in Scotland. If the authority of the board over the parish councils be supreme, as it ought to be, this improved diet will be everywhere adopted, and this whole matter will illustrate in an admirable way the efficient discharge of duty on the part of the medical officer and of the authorities under whom he acts, and at the same time the conferring of most important benefits upon the inmates of our poorhouses."

Conclusion.—With regard to the whole question of the relationships of the medical profession and the community, the speaker summed up by saying that "what we have to do in order to secure its perfect fulfilment is to discharge our part conscientiously and to the utmost of our ability. It is not by banding ourselves like a trades union and crying aloud about our wrongs, real or imaginary, but by the efficient discharge of our own duty that we shall in the end succeed. When each of us does his best for every patient and for the state, not with eye service as men pleasers, which we are so often tempted to be, but with a profound appreciation of our grave and sometimes awful responsibilities, shall we win the public esteem which will bring to our beloved science and art and to us the recognition to which they and we are entitled."

Address in Medicine.—Dr. Thomas Richard Fraser, beginning his address, said that when the association last met in Edinburgh the address in medicine was delivered by Dr. Warburton Begbie, who took for his thesis the inquiry, "Has the Practice of Medicine Made a Single Step since the Time of Hippocrates?" From his elaborate survey of the history of medicine, Dr. Begbie concluded that no general doctrine—chemical, physical, humoral, or physiological—had been propounded which satisfactorily explained the nature and production of disease; that therapeutic advancement had been obtained chiefly by the observation of patients, by adhesion to the classic method of rational empiricism; and that by this method such valuable accessions to the means of treating disease had been gained as the administration of turpentine in pulmonary gangrene and bronchitic affections; of quinine in intermittent fever; of iodide of potassium in syphilitic periostitis and thoracic aneurism; of bromide of potassium in epilepsy; and of cod-liver oil in pulmonary tubercle. Dr. Fraser thought it would not be without interest to consider to-day how far, and in what directions, medicine has chiefly advanced since Dr. Begbie delivered his address. The intervening period is the relatively brief one of scarcely a quarter of a century. It has, however, been signalized by a great increase of knowledge regarding the fundamental sciences of chemistry, physiology, and morbid anatomy; by the creation of pharmacology as a science of the action of remedies, by steady advance in symptomatology and diagnosis, and, above all, by so remarkable a development in our conceptions of the nature and production of many diseases that we appear almost to have attained a position, vainly sought for during centuries by our predecessors, of being able to formulate a doctrine of disease, sufficient to explain many of its forms, and to provide us with means for its prevention and treament.

It cannot be forgotten that the necessary pioneer work was undertaken amid difficulties of exploration in dark and unknown regions; and that but for this pioneer work the present generation would not have been able to reap so prolific a harvest of medical discovery. This indebtedness to our predecessors is nowhere more conspicuously shown than in the advancements that have been made in the diagnosis of disease. Observation, careful and intelligent, as practised by the fathers of medicine, had already constructed a nosology sufficient to distinguish the great majority of diseases, and so complete that it is doubtful if much advance could have been made if the methods in use at the commencement of this quarter of a century had alone been trusted to. The introduction, however, of physical aids to our senses, and of chemical applications and methods—each rendered possible by the growth of collateral science—has placed us in a position from which we have been able to advance in accuracy of diagnosis, and even in the discovery of new diseases.

By the apparatus now in use for blood determinations the condition of this fluid in regard to many of its most important constituents can be exactly determined, and information can be obtained valuable for treatment, and previously unattainable by any perfection of intelligent observation by means of the unaided senses. By means of the sphygmograph the physician is enabled to appreciate changes which are not only of the highest value in prognosis, but are also frequently sufficient either in themselves, or aided by the most superficial of further observation, to justify without auscultation the diagnosis of the cardiac lesion which is present. The ophthalmoscope has increased the certainty of diagnosis of many nervous affections and toxic processes, and some of the difficulties of clinical observation have been overcome by the radiograph, whose capabilities, however, are as yet undeveloped.

By the introduction of chemical processes applied especially to the examination of the stomach contents, and of the urinary and other secretions, diagnosis has also been advanced. The agglutinating effects of the blood serum in certain infectious diseases, as typhoid, Malta, and relapsing fevers, and in cholera and anthrax, upon their respective pathogenic organisms, and the application of chemical pigments to reveal the existence of the microscopically minute organisms of such diseases as pulmonary tubercle, pneumonia, and diphtheria, have removed many of the perplexities of diagnosis and rendered identification almost a mechanical art.

Diagnosis, however, deals only with symptoms, and until the true nature or course of the disease has been determined progress in treatment can be only tardy and unsatisfactory. There has been of late a great advance in the diagnosis of diseases of the nervous system, but it must be admitted that the gain to the patient from all this is in most cases very slight. The natural course of the disease is no doubt often beneficially modified, but usually to only a slight extent, unless surgical treatment is successfully applied, which is possible in relatively few cases. In those cases, however, in which it is possible to determine the actual cause of the disease, when remedies are employed which have been proved to be curative as regards that cause, the disease may in many instances be arrested in its progress, or may even be cured, provided the affected tissues have not already undergone incurable destruction.

The Toxic Causation of Disease.—It is especially interesting to recognize that the latter gratifying results are to be obtained when there is reason to believe that the disease has been caused by a toxic substance present in the body. Many of the more common poisons produce changes in structure closely simulating the changes of disease, as the peripheral neuritis, anterior cornual degeneration, granulo-fatty degeneration, and arterial sclerosis of lead; the liver steatosis and yellow atrophy of phosphorus, and the fatty degeneration and diffuse sclerotic hyperplasia of the liver; the peripheral neuritis and the atheromatous changes produced by alcohol in blood-vessels. By such facts it is strongly suggested that the structural changes found in many diseases may, after all, be mere manifestations of the action of a toxic substance. This idea is rapidly becoming the prominent doctrine of the pres-

ent-day conception of disease, and as investigation proceeds it is almost daily receiving support from new facts. Many of the poisons produced in the body, such as the ptomains and leucomains, are of the chemical nature of the previously known alkaloids, and not a few of them rival the vegetable alkaloids in toxic power and reproduce their leading effects. Nervin, for instance, is lethal in minute doses, and acts in many respects like pilocarpine; while muscarin finds its analogue in the active principle elaborated by poisonous fungi.

The organism, even in a state of health, is a veritable storehouse of these toxic substances. Many of its normal constituents are well-recognized poisons; many of the products of its glands contain toxic ingredients. Many of the substances formed in the processes of disassimilation are capable of disordering health, and even of endangering life; and in disorders of function, even if they amount to little more than mere disturbance of nutrition, poisons not found in the healthy body are generated, and produce the symptoms of disease.

The doctrine of the toxic origin of disease has also been applied to mental affections. Auto-intoxication from poisons produced in the intestinal canal is believed to be an important factor in the causation of insanity, and already neurologists, such as Nissl and Van Gieson, have expressed the opinion that the toxæmic theory is destined to clear away much of the present vagueness regarding the pathogenesis of mental disease. Further, it is not improbable that in cancer, auto-intoxication by a poison generated in the cancer cells, equally with and in some instances to a greater extent than structural degenerations of invaded tissues, accounts for the symptoms and for the fatal termination—a probability which has been strengthened by the separation from cancer of a substance possessing a hyperthermic and powerfully lethal action.

The widely acting pathogenic influence of poisonous substances has, however, received its most definite and convincing support from the remarkable discoveries in bacteriology which have signalized this period. The pathogenic action of microbes was at first attributed either to mechanical obstruction of the blood-vessels, caused by their accumulation in them, or to a biological action which enabled them to appropriate nutritive materials destined for the tissues of the body, and thus to deprive these tissues of life. It was subsequently proved, however, that their effects are mainly caused by the poisons which they produce. These poisons are of complex composition; some are alkaloids, and others modified proteids, and others, again, have altogether unknown chemical composition; and many of them are of extreme and almost indefinitely great activity. Like other poisons, they also are capable of producing structural changes. The doctrine of the toxic origin of infectious diseases is supported by an abundance of convincing facts; and it may confidently be anticipated that it will have an endurance which former systems of medicine have not possessed.

Large numbers of disease-producing poisons are thus ever present in the body, created by the normal processes of life, and abundantly produced by departures, even in themselves unimportant, from these processes. Many substances well known to have poisonous properties are intentionally introduced into the body, such as alcohol, tobacco, tea, and opium, while others, such as lead, accidentally find their way into it. The respiratory passages and intestinal canal are crowded with micro-organisms; they teem in the soil, air, and articles of food; many of them are producers of virulent poisons, and when they effect a lodgement in the body and find conditions congenial to development, they proliferate with so great rapidity that a single bacterium may in twenty-four hours have multiplied itself into many millions of separate toxin-creating organisms. In these circumstances it is of interest to inquire what defence we can oppose to these disease and death producing poisons. Instances have long been known of a possession of defensive powers against the ordinary poisons, organic and inorganic. Certain animals are able to receive with impunity large quantities of poisons, which in minute quantities are hurtful to other animals, as is well exemplified in the enormous quantities of belladonna and opium which may be administered without injury to herbivora. It is also notorious that man and other animals may become so habituated to the action of several toxic substances that in the course of time doses greatly in excess of the minimum lethal are no longer able to cause death or even much inconvenience. Explanations for these exceptional powers of defence have been found in the special activity of the processes of elimination, whereby the quantity of poison requisite to cause injury is prevented from being present in the blood; in an unusual power of producing decomposition, probably dependent on special chemical conditions of the blood; and on the property which certain organs, and especially the liver, possess of absorbing and retaining toxic substances. In the case of many organic poisons, absorption and diffusion are impeded by the walls of cells. These explanations, however, do not account for all the observed phenomena, and it must in the mean time be assumed that tissues may gradually become accustomed, possibly by exhaustion, to the perturbations produced by substances which modify their normal condition, so that by and by a tolerance is induced.

Acquired Immunity.—It had long been known that many infectious diseases conferred upon those who had suffered from them a power of resistance against subsequent attacks of the same disease. After the discovery had been made of the microbic origin of infective diseases, it was experimentally shown that if the microbes constituting the cause of any infective disease were inoculated into animals, not only were symptoms of the disease produced, but also the animal, if it survived, acquired a power of successfully resisting the morbific influence of the same microbes subsequently inoculated. It had likewise been found that each of these events could be reproduced by the filtered, and therefore microbe-free, solution in which the pathogenic microbes had been cultivated, and thus it had been demonstrated that neither the original disease nor the subsequently acquired production was actually due to the microbe, but to toxic substances produced by it.

From this position the further great discovery was made that the blood serum of protected animals, itself destitute of poisonous properties, when introduced into non-protected animals, conferred upon them a resisting power which might be so great that even large lethal doses of the virulent micro-organism and of its toxin no longer produced death or even symptoms of poisoning.

These remarkable results irrefutably demonstrate that infectious diseases are in their essence poisonings; they throw much light on the mystery of the nature of the protection acquired by attacks of infectious disease or conferred by vaccination; and they have not only at once led to valuable therapeutic results, but they indicate further applications, both in the prevention and treatment of disease, exceeding in their possibilities any expectations that had previously been originated by discovery in medical science.

As in the case of some of the ordinary poisons, mineral and vegetable, it may be admitted that a portion of the acquired protection is due to the tolerance brought about by the accustoming of the structures of

the body to the action of the poison; but this tolerance could not continue for the long periods during which acquired immunity sometimes persists after the infectious disease has been recovered from. It may also be admitted that pathogenic micro-organisms absorb and thus remove from the body certain constituents necessary for their growth and vitality, whose removal may render the body unsuited for the further growth of these organisms; but it is inconceivable that this cause could operate in the bodies of animals, which so rapidly change the composition of all their constituent parts, and that therefore the substances which have been removed would not very soon be again restored to the body, and thus render it vulnerable to fresh infections. The doctrine of phagocytosis, enunciated by Metchnikoff, in which protection is attributed to the power possessed by leucocytes of absorbing and destroying microbes, may to a limited extent account for the destruction of living microbes, and probably to a greater extent for their disappearance after life is extinct, but it can have little influence upon the soluble toxins, which have been proved to be in most cases the true cause of the disease symptoms.

The micro-organism of an infectious disease introduced into the body produces the characteristic symptoms of the disease, and if the animal recover he is found to have become protected against the disease, and in the case of the majority of infectious diseases the immunity lasts for many years. The pathogenic organism of the same disease cultivated outside the body produces a toxin which when administered to an animal likewise reproduces the symptoms of the disease; and if the animal recover, and further quantities of the toxin are successively administered, an immunity may be acquired so great that the animal suffers but little inconvenience when fifty times the minimum lethal dose or even a larger quantity of this toxin is now administered to it. The immunity acquired in the latter case is, however, brief compared with the immunity produced by the microbe from which the toxin had originated. In the case of the venoms of serpents—which in composition and in other important respects are analogous to the toxins of disease—the duration of immunity has been defined, and experiments have shown that if an animal be protected so as to survive the minimum lethal dose of the cobra venom, the protection produced against the same dose of venom does not last longer than a few hours; and even when the process of the immunization has been carried so far that the animal can survive four times the minimum lethal, the protection against this dose of venom exists for only thirty days. The protecting substance, antitoxin or antivenin, which appears in the blood after inoculation with pathogenic microbes, or after the injection of toxins or venoms, is chemically unstable, and is subject also to the general process of elimination. Its presence in the body is to be measured by days only, but the protection produced in a patient by an infectious disease may apparently endure for a lifetime, and the immunity from small-pox gained by vaccination for at least seven years. It appears to be impossible to explain these contrasting facts on any other supposition than that in the instances of prolonged immunity successive supplies of the antitoxin of the disease must be furnished to the body during the time that protection continues. It is not possible, however, that these supplies could emanate from the pathogenic organism itself, for the life of the host would not endure were they retained in the body in their condition of original virulence. Jenner himself believed that vaccina is a modified small-pox. The microbe of small-pox, like all other microbes, is greatly influenced by its surroundings when transferred from man to the calf. It is now known that it may gradually acquire the characteristics of vaccina, and elaborate substances which reproduce in man the protective effects of inoculation with human vaccine. The microbe of small-pox, therefore, has obviously become so modified that, while it can no longer produce a virulent toxin, it still retains the power of elaborating a protective antitoxin, and also retains sufficient vitality to reproduce its like through many generations in the human body.

Evidence pointing in the same direction has been obtained with other pathogenic microbes. Pasteur found that the microbe of fowl cholera, when treated in a certain manner, can have its virulence greatly lessened, and if it be then injected into the tissues of fowls only slight poisoning is produced. From fowls thus treated microbes are obtained also capable of producing only slight poisoning, and inoculations can be carried through a successive series of fowls with a like result. Each of these fowls has by this inoculation with a weakened or attenuated microbe become protected against the original and virulent microbe. In the case of the pathogenic micro-organism of anthrax, Pasteur discovered similar facts. If grown outside of the body at a temperature of 42.5° C. for eight days, this microbe could no longer produce the disease in susceptible animals, but it endowed them with a certain degree of protection against the original virulent microbe. Similar results were obtained with the microbe of hog fever, and it is important to note that a duration of immunity exceeding that known to be produced by any toxin was obtained, for the protection following inoculation of the attenuated microbe lasted for at least one year.

These instances are sufficient to show that immunity equally with poisoning is dependent upon a soluble substance produced by the micro-organisms; that the duration of even a high degree of immunity resulting from the introduction into the body of the immunizing substance as distinguished from the microbe is only of brief duration; and accordingly, with the existing evidence, it is impossible to account for the prolonged immunity following upon the recovery from many infective diseases, or from inoculation with vaccine lymph, otherwise than by assuming that so long as immunity continues the microbic sources of infective disease continue to exist in an attenuated form in the protected body.

Attenuation for the purposes of protection would therefore appear to be essentially a process in which the condition of life of the microbe is so modified that its capacity for manufacturing poisons is weakened or destroyed, while its disease-preventing properties are retained. Unless by education we can so tame and civilize a pathogenic microbe as to subdue its virulent and hostile disposition, while at the same time its beneficial and protective properties are left unimpaired, the hope of obtaining—as for plague, cholera, and tubercle—immunizing vaccines equal in efficiency to the lymph of vaccina will probably never be realized. The theory here suggested implies that long-enduring protection from infective disease cannot be obtained by the introduction into the body of either the poisonous or immunizing products of microbes—the toxins or antitoxins—but only by inoculation of such microbes as are capable in the body of assuming a non-virulent form, or of the microbe already converted into this form.

As having possibly a practical bearing upon the success of vaccination, Dr. Fraser said, in reference to the preservation of vaccine virus in glycerin, that it must not be overlooked that the powerful microbicidal action of glycerin upon the contaminating organisms of this lymph may in the course of time weaken or even destroy the activity of the specific organism by which the protection against small-pox is produced.

In the case of some diseases it is possible that the modification of the pathogenic power of the micro-organism necessary to convert it from a poison-producing to an antidote-producing agent cannot be accomplished in the body. Thus may be explained the failure of certain diseases to protect the body from subsequent attacks of the same disease, well recognized in the instances of pneumonia, influenza, rheumatic fever, and tubercle. On the other hand, the microbes of other diseases may in small numbers, and attenuated both in virulence and in power of conferring protection, persist in the body after convalescence has been established, and actually render it not only more susceptible to fresh infection, but also to a recurrence of the disease by auto-infection. Results obtained by experiments with snake venom support the former possibility, for, owing to some as yet unexplained individual peculiarity, an animal which has received a number of successive doses of venom, each considerably below the minimum lethal, instead of having thereby acquired protection, may unexpectedly exhibit serious symptoms of poisoning, and may even die when it receives a dose considerably below that required to produce death in an animal which had not previously received any venom.

Further, pathogenic microbes attenuated as to their virulence, but not as to their protective power, may enter the body, and render it immune by a process of accidental vaccination, and thus may be explained, without recourse to such unsatisfactory phrases as individual or racial peculiarities, well-authenticated examples, known to all of us, of repeated exposure to infection without the production of disease, and of the immunity enjoyed by the inhabitants of towns and districts daily subjected to the virus of typhoid fever, malaria, or yellow fever.

Address in Surgery.—Mr. Thomas Annandale, of Edinburgh, delivered the address, taking as his theme, "The Present Position of Surgery." There are now few diseased conditions, he said, in which surgery does not play a very essential part in connection with treatment, and there is scarcely a single organ of the body, internal or external, which is not the subject of successful surgical procedure. The brain, the organs of the chest, abdomen, pelvis—many of which were so long looked upon as belonging solely to the province of the physician—are now shared, if not absorbed, by the surgeon as regards the relief or cure of their diseases.

The Scientific Aspect of Modern Surgery.—It must be acknowledged, the speaker said, that for the marvellous advances in connection with present surgical practice we are largely indebted to those who have carried on experimental and other research in connection with the sciences of chemistry, physiology, bacteriology, anatomy, and pathology.

In the early stages of antiseptic surgery failures undoubtedly occurred, but such failures when honestly investigated were important as lessons, and the consideration of their causes did much to establish on a successful basis the great principle. There were some who, ignoring the principle of the antiseptic treatment and also ignoring the established principles of surgery, preached and practised that the mere application of carbolic acid or other antiseptic lotion was all that was required, and when such treatment was unsuccessful condemned the whole system. Twenty-one years ago Mr. Annandale had said: "It is not the mere application of carbolic acid in one form or another which constitutes the antiseptic treatment, but the true antiseptic surgery is that which is the result of many years' patient, thoughtful, and scientific research; of vast, laborious, and expensive experiments, and of much and valuable time spent in clinical observation on the part of Mr. Lister." No one rejoiced more than Lister himself when it was proved that his great system could be successfully simplified, and so used under circumstances which formerly made it difficult or impossible to carry it out.

But while the external application of antiseptic means and precautions is now thoroughly established upon a simple and at the same time efficient basis, it must not be forgotten that injurious organisms enter the body and tissues by other channels than through external wounds or breaches of surface; and therefore it is that the science of bacteriology becomes so important. We have learned that organisms of various kinds gain entrance into the tissues or organs of the body, and that some special condition of these tissues and organs favors their development and multiplication. In the majority of instances the bad effects are produced not so much by the multiplication of the organisms themselves as by poisons or toxins caused by their presence or behavior in connection with the tissues. Further, it would appear that the resulting toxin may not itself be the poison, but give rise to chemical changes and products which are the real cause of the injurious results. It is also an interesting fact that the presence of more than one form of bacillus may either increase or destroy these injurious results.

Continued careful study of anatomy and pathology and accurate clinical observation should do something to increase our knowledge, but the speaker believed that much of our future trust for light must be in connection with physiological chemistry, which we hope may be able to teach us more of the origin, causation, and behavior of the various toxins, and of the action of the tissues in connection with them, so that we may be able to counteract their injurious effects by appropriate treatment.

At the present time we endeavor to treat the general effect of these toxins, either by the administration of remedies supposed to produce a general antiseptic effect or by the introduction into the tissues by subcutaneous injection of so-called antitoxins. This latter treatment has met with an encouraging amount of success, especially in certain directions; but its position is still uncertain, and much further experience is required to place it on a safe and reliable foundation. All who have employed the antitoxins in connection with surgical conditions must have encountered this uncertainty as to their action. In the speaker's experience some severe cases of septicæmia had recovered after the injection of an antitoxin, but other cases very similar had recovered without any antitoxin being used.

Another important subject for further study is the physiological action or connection bteween one tissue or one organ and another. May not further experience of this connection help us in carrying out treatment based upon this connection? Having thought it his duty to test the suggestion of Beatson for removing the ovaries in cancer of the female breast, incurable by other means, the speaker carried it out in three typical cases, and his experience was that, though the disease was not cured, the removal of the ovaries had certainly some influence upon the diseased local condition.

The remarkable results obtained by the use of thyroid extract should be an encouragement, and it has already been proved that certain vegetable products act as powerful antitoxins. If it can be discovered that certain drugs can be safely and successfully used as antitoxins, it will much simplify our treatment, for such remedies can be more easily and more certainly handled than the antitoxins now in use.

The treatment of sarcoma or other new growths by means of toxins is another subject of great interest to the surgeon. The results obtained by Coley and oth-

ers by the mixed toxins of streptococcus and prodigiosus give cause for hope, for under the use of these toxins growths have undoubtedly disappeared, but sarcomas and other growths do occasionally undergo a check in their development, and even disappear without any apparent cause. In all probability these occasional occurrences are the result of some physiological or bacteriological action which is not perceptible.

The Practical Aspect of Modern Surgery.—If asked to define any special characteristic which will apply to the practice of surgery at the present day, the speaker would be inclined to say simplicity—antisepticity of course being granted—a simplicity in which are included operative procedure, instrumental assistance, and after-treatment. It is true that from time to time new procedures and new instruments are suggested, but as a rule it will be found that if practical surgeons adopt and employ them they are in the direction of continued simplicity with some addition to their efficiency.

The practice of surgery has not only reached a high standard of improvement, but it has much widened its area as regards both the number of its procedures and the number of those who practise them. Lately surgery proper and what is called gynæcology have been gradually merged into one another, so that the line of demarcation between them is scarcely apparent. Both require for their proper and successful performance that training and those qualities which make the good surgeon. That physicians under the designation of gynæcologists should now become operating surgeons is perhaps only a little return for the fact that surgeons have so extensively and successfully invaded the province of physicians, and as time goes on some balance may perhaps be arrived at which, while guarding the interests of the public, will satisfy the representatives of medicine and surgery.

In referring to anæsthetics, Mr. Annandale expressed the opinion that chloroform held the field as the best general anæsthetic in connection with surgical procedures; and although he had met with a few fatal results from its administration, he had most thorough confidence in its safety if carefully used and its effects diligently watched. Fatal results will occasionally take place in connection with all anæsthetics, and these fatal cases may be divided into (1) avoidable, (2) unavoidable. The avoidable ones are those which are due to careless administration or to neglect of means to prevent blood or other matters entering the air passages. The unavoidable cases are the result of heart failure from fatty or other conditions, and occasionally they may be caused by cerebral conditions. In the majority of these unavoidable cases it is impossible by any external examination prior to giving the anæsthetic to discover the condition which has led to the fatal result.

The Moral Aspect of Modern Surgery.—The speaker said he would make no apology for offering a few remarks under this head, for he was decidedly of opinion that it becomes every member of our profession who has the true sense of relieving suffering humanity at heart, and who desires to maintain the honor and reputation of his profession, to speak out with no uncertain meaning in regard to every action which is dishonest or dishonorable or tends to be so. It is sincerely to be regretted that in some quarters the true, honest, and high feeling which should be the standard principles of the members of our profession is in the present day partially or wholly ignored, and in consequence the profession is not always respected as it should be and its members are looked upon by some as mere humbugs, in some cases not without reason, thinking more of fees and fee accumulations than of their patients' cure or relief.

Three causes influence this much-to-be-lamented evil which has insidiously invaded our profession, namely: 1, active competition; 2, untrained specialism; and 3, society demands.

There can be no doubt that the number of medical practitioners has increased, but the number of medical men as compared with the population is very little changed from what it was twenty years ago. The active competition is not so much due to the increase of medical men as to the fact that in many instances the most of the remunerative work is done by a few, which leaves much hard work and poor pay for the remainder of the profession.

The second cause is untrained specialism. Honest specialism has aided much the practice of surgery, and by honest the speaker meant such practice as is founded upon a thorough knowledge of all the different departments of the profession, and upon an honest study of all the circumstances connected with the various conditions which affect the organ or organs which are specialized. Specialism in the hands of qualified members of the profession, unless practised under these conditions, is simply quackery, and quackery of the worst kind, for it is carried on by those whom the public understand to be properly educated as regards their profession.

The third cause is society demands. A section of the public, or rather a section of what is termed "society," has done much to interfere with the proper feeling which should exist in our profession. The manners, qualifications, and doings of members of the profession are freely criticised at afternoon teas and other entertainments. One man is condemned and some supposed failures in treatment are magnified or invented, while another receives extravagant praise and many of his wonderful surgical or other procedures are lauded and not infrequently described, with marvellous details added. One is glad to think that in the majority of instances the surgeon or specialist has no art or part in such proceedings; but there are some who take advantage of such extravagant popularity, and, having become the fashion, trade upon it in a manner which is not consistent with the high feelings which should influence all our professional relationships. If any member of our profession encourages or takes part in society's ignoble life or actions, he is not worthy to belong to the profession and he certainly does not add to its reputation.

Address in Psychology.—Sir John Batty Tuke, of Edinburgh, delivered this address, taking as his title "Modern Conceptions of the Etiology of the Insanities." It was inevitable that from the earliest down to quite recent times the study of the insanities should be carried out on psychological lines. The prominence of the mental symptoms asserted itself, and cases of insanity were classified under the terms mania, melancholia, and dementia. Notwithstanding that these so-called forms were based on mere external appearances, these terms assumed the proportion of diseases. The symptom was the essence of the case, and the underlying causating condition was ignored. Undoubtedly to the public and the lawyer, the mental symptoms must always be the essence of the case; but to the physician they are not. He has to go farther back and seek for the *fons et origo mali*. Still in the hands of Pinel and his school the psychological method of study subserved important purposes; but this undivided adherence to the psychological principle of study led to "an undue love of minute detail," and consequently to undue extension. Instances in which intellectual deficiencies were not so apparent as changes in feeling and conduct were designated cases of "moral insanity," with such subclasses as pyromania, erotomania, kleptomania, homicidal and suicidal mania, and so on, irrespective of the clinical observation that no case of insanity exists without moral aberration, and that in

those cases in which moral obliquity is most prominent the intellectual faculty is also weakened, inasmuch as the patient is not able to recognize the nature of his immoral acts or weigh their consequences. Thus confusion became worse confounded, and fallacies arose within the psychological conception itself.

It is only during the last thirty-five years that the study of the insanities has ceased to be so distinguished, or at least that scientific data have been afforded which should prevent it being so distinguished, data which, although still far from perfect, have afforded starting-points to the psychiatric physician for the scientific study of his subject. It is of interest and importance to contrast the state of knowledge of the anatomy and physiology of the cerebral hemispheres in 1864 with that of 1898. Up to the former year even the rough naked-eye anatomy of the convolutions was chaotic, only some two or three gyri being recognized as distinct anatomical landmarks.

Great as has been the work of the anatomist, that of the physiological pathologist has been equally important. Hughlings Jackson's name must ever hold the foremost place in this department of science, and Fritsch, Hitzig, Ferrier, and Gowers would be the first to acknowledge that his induction opened up that field of inquiry which has been of such importance to the study of nervous physiology and pathology.

The physiologists of the psycho-physical school which arose as a result of scientific developments advanced the study of psychology so far as they ranged scientific data so as to add to the "provisional body of propositions" about states of mind necessary for their philosophy. Whether our knowledge of states of mind has been materially increased by the lucubrations of this school is open to question, but there can be no doubt that the views not only of the physiologist, but of all thinking men, have been enlarged by the application of the philosophic mind to the scientific position. Were it only that the world has had placed before it the proposition that the essence of mental life and the essence of bodily life are the same —namely, the adjustment of inner to outer relations— great gain has accrued to science and philosophy. But the change of conception of the nature of the insanities is much more due to the establishment of scientific data bearing on the antecedents of mental action than to the generalizations of the philosopher as to mental activities.

Time, the speaker said, would permit him only to allude to the observation around which all others centre—that is, the demonstration of the mechanism by which impulses are carried from the periphery to the cortex and from the cortex to the periphery. We know that series of fibres exist which, starting from the entire surface of the body, the muscles, and from the mucous membranes, are collected in the spinal cord, and pass upward to the optic thalami, whence they are distributed in three systems to the cortex. To take as an illustration only one of these "sensory" systems—that which passes directly to the Rolandic cortex without forming connections in its upward course with any other system of fibres. In the external layers of the gray matter these fibres come into relation with the dendrites of the pyramidal cells; but there is no anatomical continuity between the sensory fibres and the dendrons; they transfer impulses by contact. It is contended that the liberation of energy takes place in the dendrons, which, by their gemmulæ, are in close contact with the dendrons of other cells, forming what Foster terms "synapses." Be this as it may, impulses descend to the cell bodies, through which certain of the fibrils of the dendron pass to the descending axon—till lately spoken of as the axis cylinder—the fibrils of which are distributed to the periphery, throwing off collaterals to remote areas of the cortex. In order to obtain and maintain the conception of the mechanism of a circuit it might be well not to restrict the term "neuron" to the cell body and its dendritic processes, but to include in the term the ascending conducting apparatus, the cell body, and the spinal, cerebellar, and cerebral distributing arcs, and to regard the whole apparatus as a physiological if not an anatomical unit.

It is not necessary to consider where and how the transmutation of peripheral impulses takes place, but it is of importance to emphasize the statement that impulses are not generated in the cell body. As Gowers says, the old battery idea must be thrown aside. It may be regarded as the "vital centre" of the neuron, and, making allowances for the possible action of the dendrons, it may be held to be a receiver, conservator, and transmutator of energy, and a liberator and distributor of energy by means of its synapses with other pyramidal cells and, what is of supreme importance, with association cells. But all impulses come from without—a fact which must have important bearings on the question of the adjustment of outer to inner relations.

It is as difficult to estimate the influence of the developments of knowledge of the nervous system on the individual general physician as it is to gauge the influence of bacteriology. Our acquaintance with both these subjects is a recent acquisition. The latter is a new science, and in the case of many of us only its outlines are present with us. But its principles pervade the method of thought of the whole profession. So with the study of the minute anatomy of the brain: none but experts can be expected to be acquainted with the full details of its anatomy, but the great leading facts as to structure, and the facts, theories, and warrantable assumptions as to its actions have operated, and continue to operate, on the views of the specialty at large.

A strong indication of the awaking of the scientific spirit is afforded by the earnestness with which the study of the morbid anatomy of the brain is being prosecuted by the psychiatrist all the world over. The value of research into morbid cerebral anatomy has made itself so strongly felt that laboratories have been established in many asylums. As a consequence of this system of study, a vast change has come over the aspect of psychiatric literature. The journals of the day, instead of dealing largely with analyses of the mental condition of real or imaginary persons, with abstract considerations, and mere clinical details, are now mainly occupied by papers of a strictly scientific character bearing on the production of neuroses, and the reports of cases are rarely confined to a mere description of symptoms.

But the all-important question remains to be answered: What effect has the change in the principles of study had on general pathology, practice, and treatment? As regards general pathology the evidence is manifold. In former times the theory of the effect of the mind on the body held a foremost place and gave rise to many misconceptions; but now we recognize that the brain exercises trophesial functions over all the organs of the body, and we are alive to the fact that general degradations are referable to imperfect brain action, that they are secondary to the reduction of its nourishing action, and are to be treated accordingly.

In most of the recently erected institutions for the insane, at home and abroad, we find separate hospitals provided for the treatment of recent and acute cases. This surely marks the reduction of theory to practice. Instead of the subject of a recent attack of insanity being mixed up with the residuum of chronic cases, he is placed in a separate institution, where he is submitted to systematic treatment on thoroughly hospital

principles. But even with such appliances many of those working among the insane are heavily handicapped, as no provision is made by the public for the treatment of cases in the initial stages. Statistics show that the increase of chronic lunatics occurs among the poorer classes of society, and not among the rich. This is due to the latter being able to place members of their class showing indications of incipient insanity under systematic treatment at home during the prodromal stage; while the former are compelled to allow matters to drift till cases become more or less confirmed. If we exclude general paralysis and epileptic insanity from consideration, at least eighty per cent. of recent cases are amenable to treatment. But such treatment is necessarily costly, as it involves nursing, possible change of residence, and continuous medical attendance. This is out of the power of the poor to obtain. All general hospitals shut their doors against persons suspected of insanity, but the asylums cannot receive cases until the symptoms are so far advanced as to warrant certification; and, in England especially, the procedure for the transmission of insane persons to asylums is so absurdly cumbrous as to prevent many persons being placed under treatment until such time as the probabilities of recovery are seriously lessened or the case is hopeless.

If teachers conduct their courses of instruction on the general principles which govern the teaching of medicine, the general practitioner will soon be found treating the insanities as he does every-day disease, and we may fairly anticipate a reduction of the number of cases relegated to asylums as a consequence of early and rational treatment.

OUR LONDON LETTER.

(From our Special Correspondent.)

PRINCE OF WALES SLIPS AND FRACTURES PATELLA—GOVERNMENT ABANDONS COMPULSORY VACCINATION—TEACHING TROPICAL DISEASES—THE EDINBURGH MEETING—DISPUTED WILL ON THE ALLEGATION OF HYPNOTIC INFLUENCE—MEDICAL COUNCIL—COURT PHYSICIANS—COLLEGE OF SURGEONS.

LONDON, July 22, 1898.

FRACTURE of the patella is just now interesting the public, on account of the Prince of Wales having met with this accident. Doctors are being asked all sorts of strange questions whenever the opportunity presents itself, and unless some fairly clear answer is evoked the interrogators look dissatisfied. They all seem to expect a precise prognosis as to the result and especially as to the time the prince may have to rest. One physician is putting his friends off with the statement that it is a purely surgical affair and they must apply to their surgical friends for information.

A precise statement of the case has been issued to satisfy the public anxiety. In the sudden effort to save himself from falling when he slipped on some stairs, the prince sustained a transverse fracture of the patella, near the upper margin of the bone. About one-fifth of the patella was separated, of a somewhat crescentic shape. The gap between the fragments was at first more than two inches, but in the course of four days diminished to one-fourth inch. Sir Wm. MacCormack, Sir Thomas Smith, and Sir F. Laking have charge of the patient, and yesterday Lord Lister joined in consultation, and approved everything that had been done. Of course it was a very unfortunate mishap, but so far there is reason to anticipate the best results.

The parliamentary news is most unsatisfactory. In obedience to the antivaccination agitators or worn out by their tactics, the government has given up compulsion. Step by step this strong government has climbed down on the question, but all its "graceful concessions" are no more efficacious than those it has made in other matters. The minister in charge pleaded the number of speeches made against the bill in the house, but he did not attempt to weigh them or estimate the authority of the speakers. Even after these the opponents are not content, and are going to move the rejection of the bill on the third reading. Perhaps it will be as well if they inflict a defeat on a government having a large majority, taking up an important question for the public health, and not having nerve enough to carry out its convictions. If the law is not to be improved, what is the use of meddling with it?

Sir W. Foster endeavored to carry a conscience clause, in the hope that if any sincere opponents were released from their duty to their neighbors and their own families all would work smoothly. He failed, and he appears not to have gauged the depths of the antivacs' fanaticism. His action has not had a good influence and he scarcely represents the view of the profession, though many were doubtless willing to accept the compromise and end the dispute.

The teaching of tropical diseases has come very prominently forward of late. As I have already reported to you, some of our medical schools have established lectureships on the subject. One of these has been accepted by Dr. Patrick Manson, whose book on the subject at once took the position of an authoritative manual. Mr. Chamberlain, as colonial minister, has not been oblivious to the importance of the study of tropical diseases in an empire which embraces so many climates, and he seems to consider that something more should be provided than the splendid training at Netley, which is, however, confined to medical officers of the army and the Indian forces. He is willing to make a grant from the colonial office toward meeting the need and suggests that the Seamen's Hospital might be utilized, and the *Times* has indorsed this view. The committee of the hospital is naturally desirous of such help to extend its work, and Sir H. Burdett appeals to the public for £10,000 to start and an income of £2,000 *per annum*. The hospital is not conveniently situated, and only a small proportion of the patients has hitherto been admitted for diseases that can properly be called tropical. The doubt, therefore, arises whether there will be a supply of clinical material sufficient to meet the requirements of the proposed special school. Malaria, dysentery, and sometimes beriberi may be seen there, but they are only a small part of tropical diseases. Others, especially acute cases, are rare, and a student might attend diligently for months without obtaining a practical experience of them. Still there is no telling what may be the development of a small beginning, and we may cordially wish it success.

The British Medical Association has formed a section for the Edinburgh meeting on the subject of tropical diseases. Dr. Manson is president of this new section and a number of practical papers have been promised. Three set discussions have also been arranged—viz., on unclassified fevers of the tropics; beriberi; and epidemic plague in India.

Sections on psychology and neurology have also been added this year. Altogether sixteen sections are arranged for, and the meeting, which is to occupy next week, is expected to be most successful. It can scarcely be otherwise, considering the many attractions of Edinburgh and its position as a great medical centre. Some have already started and others leave to-morrow. Those who remain are quietly discussing

the probability of getting away for the occasion or the advantages of some other form of holiday.

The case I mentioned of a will being disputed on the allegation that the deceased had been hypnotized has ended in favor of the medical man. Dr. Kingsbury, whose book on hypnotism you may be familiar with attended a lady for a considerable time. He tried to hypnotize her on several occasions, but stated in court that he always failed and according to the practice he had always inculcated invariably had a third person present. Great interest was evinced in the trial. Sir W. Broadbent and other medical men appeared among the witnesses. Under the will Dr. Kingsbury would receive some £30,000. The judge explained to the jury very carefully the law as to undue influence. The jury found that the will was duly executed, that that the deceased was of sound mind at the time it was executed, that she knew and approved its contents, and the residuary clause, so far as it benefits Dr. Kingsbury, was not obtained by undue influence.

Dr. Kingsbury is to be congratulated on the result and on the refutation of the injurious allegations levelled against him. The case shows the danger to which a medical man may be exposed by unusual gratitude expressed in the form of a legacy.

The Incorporated Law Society receives £5,000 a year to enable it to preserve the rights of the profession and maintain its honor. Dr. Farquharson asked the chancellor of the exchequer to provide a similar sum to assist the Medical Council to prosecute unregistered practitioners. The minister declines the invitation.

Sir Wm. Broadbent succeeds the late Sir R. Quain as physician extraordinary to the Queen.

Sir Wm. MacCormack, Bart., has been chosen president of the College of Surgeons for a third term. Mr. Pickering Pick and Mr. Howard Marsh are the vice-presidents for the ensuing year.

OUR BERLIN LETTER.

(From our Regular Correspondent.)

GERMAN PHYSICIANS AND THE ADMISSION OF WOMEN TO THE STUDY OF MEDICINE— BIOLOGY OF THE TUBERCLE BACILLUS—BRONCHIAL ASTHMA.

BERLIN, June 30, 1898.

THE study of medicine by women was recently the subject of a thorough discussion at the meeting of German physicians in Wiesbaden. The struggle to improve their material condition and to obtain equal rights with men has been the main factor in this rush for the scientific professions. Penzoldt, of Erlangen, the first speaker, thought that if the practice of the profession by women was at all desirable, it should not be confined to the medical profession alone. However, we need not fear that the number of female physicians will be rapidly increasing; we have but to note the figures in such countries as Sweden, where the study of medicine has been opened to them for decades. In Sweden thirty years elapsed from the passing of the enabling law until the first woman studied medicine. Penzoldt admits that woman are very diligent and capable of studying, but he regards them as far less adapted to practice. Here they are far behind the men. The friends of the woman movement claim that in certain diseases female patients only with extreme reluctance make a confidant of the male physician, and that therefore there exists a need for female physicians. Regarding this point it is shown that the German physicians with remarkably few exceptions do all they can not to wound the sensibilities of their patients. But where life and health are at stake, general customs and usage must for the time being be discarded. But Penzoldt does not believe that female patients would be any more likely to confide their delicate troubles to the female physician earlier than they would to the male, because, first, these troubles begin insidiously and imperceptibly, and secondly, the fear of an operation would tend to restrain them. The practice of children's diseases is to-day almost entirely in the hands of the male practitioner, and will probably continue so in the future, for here there is certainly no cause to withhold confidence. The prospects for the female practitioner are therefore not bright. If, however, women are to be admitted to the study of medicine, we ought at least to have the right to demand that the other professional studies be open to them, especially dentistry and pharmacy. And midwifery might be raised to a higher standard by the entrance of educated women. Penzoldt is an outspoken opponent of the admission of women to the study of medicine. While some speakers expressed themselves similarly, others declared there should be equal rights to all. Becker, of Berlin, wants the sexes to have equal rights; every one should be permitted to accomplish what he or she can. The woman movement has been started and no theses or resolutions can stop it. Finally the following resolutions were adopted by the society, which represents thirteen thousand and eighty-six physicians: 1. At present and until the law is more leniently framed for them, we need expect no more active participation from the women to be admitted to study medicine. 2. Should there be a more active participation on their part, it will result in more harm than good to the patients, and to the women themselves; there will be no benefit to German science, there will be a lowering of the medical dignity, and no advancement of the general welfare may be expected from such a source. For these reasons the society holds it undesirable that the first attempt to admit women to the study of the learned professions should be made in medicine. At least there should be a demand made to admit them at the same time to the study of all the professions. The following was added to these resolutions: The previous education, preparation, and examination must be the same for the women as for the men; especially must women not be admitted to the study of single branches of medicine, but equally with the men should be examined in all branches of medicine and surgery. The "Aerztertag" has been accused of having acted from a one-sided and self-interested narrow policy, and this opinion has been voiced in almost all the daily papers. Indeed, all signs indicate that the beginning of the new century will witness the unrestricted admission of women to the study of medicine.

Aronson communicated to the Berliner medicinische Gesellschaft at a recent meeting a most important contribution to the biology of the tubercle bacillus. Aronson first made mass cultures of this bacillus, obtaining in all about three hundred grams of pure growth. This he extracted with alcohol and ether. The ethereal extract when evaporated left a brownish, stringy mass behind, which equalled twenty or twenty-five per cent. of the total mass of original culture. Chemical examination of this mass showed that it was not, as Klebs had assumed, a fat, but that it contained seventeen per cent. of free fatty acids, while the remainder was a pure wax. The bacillus forms this wax even when grown upon inorganic culture media. It has staining-properties similar to the bacillus, *e.g.*, it stains with carbol fuchsin, which, however, is not set free or only with great difficulty in hydrochloric alcohol. Aronson was able also to obtain a similar substance from diphtheria bacilli, which substance exhibits, however, the same peculiar staining-properties with carbol fuchsin. The wax of the tubercle bacilli occurs mostly between but also in part in the bacilli

themselves; hence the fact that sections and other preparations of these, even though treated with alcohol, xylol, etc., still take up the stain.

At the Verein für innere Medicin Fränkel read a paper on bronchial asthma, with special reference to its so little understood pathology. He had had the opportunity of a careful study upon a patient. A man, sixty years of age, who came into the hospital for gout, had been suffering for the previous year from attacks of bronchial asthma. He died in one such attack. The autopsy showed emphysema, and enlarged small and medium-sized bronchial tubes, which were choked up with cylindrical epithelia. Besides these there were spirals. Fränkel can find no satisfactory explanation for this desquamative catarrh. At all events, when we take into consideration autopsy reports of other cases of bronchial asthma, we must arrive at the conclusion that there can be no question as to the variety of changes taking place in this disease, there can be no uniform picture in the tubes. Therapeutically, Fränkel would recommend a subcutaneous injection of hyoscyamus hydrobromate, he having obtained a very good effect from one-half to one milligram injections in another severe case.

THE MEDICAL DEPARTMENT OF THE ARMY.

To the Editor of the Medical Record.

Sir: It is a matter of great surprise to me that a leading medical journal should condemn the medical department of the army, without a hearing, upon the reports of newspaper correspondents. I regret that the pressure of official duties makes it impossible for me at present to make a full reply to these strictures. I will, however, take time to state a few facts.

The number of medical officers allowed by law is inadequate in times of peace. The total number allowed is one hundred and ninety-two. There are at present thirteen vacancies. The administration of the surgeon-general's office and the Army Medical Museum requires six. Eleven are on duty at medical supply depots and as chief surgeons of military departments. One is at the Soldiers' Home; fifty-six are at general hospitals, on hospital ships, and at garrisoned posts. Four have been disabled during the war by sickness. Five are on duty as chief surgeons of army corps. This leaves ninety-six medical officers available for duty with troops in the field. Of these, thirty-five have been appointed brigade-surgeons of volunteers and are distributed among the various army corps.

This deficiency in regular medical officers has made it necessary to employ nearly three hundred contract surgeons, and more are being employed every day. Most of these doctors from civil life are doing good service, and many of them are thoroughly well-equipped physicians and surgeons with ample hospital experience; but it has been impossible to make a careful selection, owing to the great pressure of business in the surgeon-general's office, and the urgency has been so great that it has not been practicable to have examining-boards to pass upon their qualifications.

General Shafter's army at Tampa was thoroughly well supplied with the necessary medicines, dressings, etc., for field service, but owing to insufficient transportation he left behind at Tampa his reserve medical supplies and ambulance corps. Every one who has read the papers knows about the difficulties encountered in landing supplies at Siboney. As is usual under such circumstances, the fighting men with their guns and the rations necessary for their subsistence were first landed and hurried to the front. The *Relief*, loaded to her utmost capacity with medical supplies, arrived at Siboney four days after the fight at El Caney. That she was not able to get there sooner was a great disappointment to me, but was no fault of the medical department. I asked for a hospital ship in good time, but there was unavoidable delay in securing a suitable vessel and in preparing her for service.

It has not been the expectation of the medical department that every wounded man would immediately receive the attention of a surgeon. No modern army makes provision for so large a number of medical officers as this would require. But attached to our army there is a corps of non-combatants known as the hospital corps, which is the organized and authorized Red Cross corps of the army. At the outbreak of the war we had eight hundred hospital-corps men in service. At present there are more than four thousand. These men wear a brassard upon the left arm, bearing the red cross of the Geneva convention. We have done our best to instruct them in giving first aid to the wounded, and in a majority of cases a first-aid dressing properly applied by one of these men is all that is required. All of the surgeons who have come from the front have testified to the remarkable results attained from the prompt application of aseptic dressings by our hospital-corps men and by the soldiers themselves or their comrades. The proper application of the dressings contained in the first-aid packet, which is carried by every soldier, is, under existing regulations, a matter in which every enlisted man has special instruction. For some time past this instruction has been given first by our medical officers to the company officers, and by them to the enlisted men.

My position with reference to the inadvisability of sending female nurses to our camps of instruction or with our armies in the field has given great offence to some members of the Red Cross Society, and it is evident that the unjust attacks which have been made upon me and upon the medical department of the army result largely from the stand I have taken in this matter. I have gladly accepted the assistance offered us in the way of delicacies for the sick, etc., and we have now a large number of trained female nurses on duty at our general hospitals, where they are giving great satisfaction; but I see no reason to change my views with reference to the sending of female nurses with our troops in the field. They are an encumbrance to an army mobilized for active operations. This objection does not apply to the sending of immune female nurses for service in our yellow-fever hospitals near Santiago, and I have already sent nearly one hundred.

The first-aid dressing is to be put on at or near the firing-line, and the men have usually to be transported to the field hospitals on litters. In this age of aseptic and conservative surgery comparatively little operating is required, and our regular force is ample to attend to this. Moreover, we have men selected for their experience and skill to decide whether operations are necessary and to perform them. I have never objected to the surgeons and ambulances of the Red Cross Society going to the field for the purpose of rendering any necessary assistance, but, in my opinion, they should be independent as regards transportation and should not call upon the government for assistance in getting to the field of operations. The editor of the Medical Record knows that when he, in company with other prominent gentlemen from New York, called upon me in my office to offer the assistance of this organization, I said that an emergency might arise in which such assistance would be most welcome, and suggested the dispatch of a hospital ship to the seat of active operations. If there has been any failure to get necessary supplies to Cuba, it has been because of the difficulty of securing adequate transportation and of landing supplies through the surf; but we have been constantly importuned to transport Red Cross agents

and female nurses to the front. I am informed that many of these so-called nurses had never received any special training to fit them for the duties they were so eager to undertake. The National Red Cross Society should have been entirely independent of government transportation, if it expected to fulfil its proper function of affording aid to the wounded of both armies in accordance with the terms of the Geneva convention.

As regards the *Seneca*, I am informed by Major Torney, in charge of the hospital ship *Relief*, that he transferred forty-two wounded men, most of whom were entirely able to take care of themselves, from the *Relief* to the *Seneca*, because at that time it was expected that our troops would storm Santiago and that a large number of wounded would be sent to the hospital ship for treatment. For the same reason a certain number of convalescents were sent from the shore hospital. Two acting assistant surgeons were sent on board with a supply of the most necessary medicines and dressings. If the ship was overcrowded or inadequately supplied with water, knives and forks, etc., the medical department is in no way responsible.

Finally, I would say that when the medical officers now at the front return home I expect to have full information with reference to the efficiency of the medical service in the vicinity of Santiago; and in the mean time I hope that the profession at large will not be so ready to draw inferences unfavorable to the medical department of the army, on the basis of reports published in the daily papers, as the editor of the MEDICAL RECORD has been.

GEORGE M. STERNBERG,
Surgeon-General, U.S.A.

WASHINGTON, August 1, 1898.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the editorial of the MEDICAL RECORD of July 30th, suspicions are thrown out reflecting on the efficiency, foresight, and proper management of the medical department of the army during the Cuban campaign. The remarks made by the editor are based, as he himself asserts, almost exclusively on a correspondence which appeared in a recent issue of *The Sun*. In commenting on this article the editorial states: "If the report is true, and there seems to be no good reason for doubting it, the army medical department appears in a very unenviable light. It is said that there was a total lack of everything necessary for the proper care of the stricken soldiers. Why this was so it is hard to explain, especially in view of the fact that the war department has constantly declared, in declining voluntary assistance from charitable organizations, that it was abundantly able to cope with any possible emergency in the field, and yet this is the result." The correspondent of *The Sun* made bold to say: "It was evident that the medical department of the army had failed absolutely to send hospital supplies, or by this time they would have been landed. On the one hand, it was pitiful. On the other, it was negligence that could have been the result only of incompetence." I am sure that if the editor of the MEDICAL RECORD had been better informed he would not have been so willing to lend his ear to a newspaper correspondent, whose success consists nowadays largely in tingeing facts with more or less imagination and sensationalism. The medical men inside and outside of the army have little if any influence over the lay press, but the editor of a medical journal of such a high standing with the medical profession throughout the entire country as has been willingly accorded the MEDICAL RECORD should take the necessary pains to investigate more thoroughly the circumstances which dictated the editorial before casting any reflections whatsoever on the chief of the medical department. Dr. George M. Sternberg is no stranger to the medical profession and the American people. He occupies the exalted position of surgeon-general of the United States army, not by political preferment or gradual ascent by promotion, but by merit. President Cleveland made a wise selection when he made the appointment. It was a selection that met with the heartiest approval on all sides. General Sternberg knows from long and actual experience what it is to be a soldier in the field. He has been there. He served with distinction during the war of the rebellion. He has followed the unruly and wily Indians over plains and mountains during many a campaign. He has investigated yellow fever at home and abroad, regardless of his own health and life. Since he has been placed in charge of the medical department of the army he has been tireless in making many much-needed improvements. The army medical school is one of the many fruits of his labors. He has taken special interest and pride in promoting the intellectual and professional advancement of his young army surgeons, by assigning them for temporary duty in large cities where they could enjoy clinical instruction and laboratory work. He has taken a deep and active interest in the organization and usefulness of the Association of Military Surgeons of the United States, and served most acceptably as president. Last year he was honored by the profession by election to the presidency of the American Medical Association. His earnest devotion to his duties made it impossible for him, to his greatest regret, to attend the Denver meeting. The name of General Sternberg is often seen on the programmes of scientific societies from the Atlantic to the Pacific and from Labrador to the Gulf. He crossed the Atlantic last summer to represent his government at the international congress held in Moscow, Russia, and his work there added much to the lustre of American medicine. Not only is the surgeon-general, now so unjustly accused of incompetency, accorded a well-deserved place in the first rank of the profession, but his administration shows executive talents which have served him well during the present campaign. He has shown good judgment in the selection of his advisers. Colonels Alden, Greenleaf, and Smart are all men of large experience and admirable executive abilities, as all can testify who have been brought in contact with them. The charge of incompetence and ignorance certainly lacks foundation in the case of General Sternberg and his administration.

Now as to facts. The correspondent of *The Sun*, who furnishes all the material for the editorial referred to, goes on to say: "The wounded were carried back from the fighting-line on stretchers, and laid on the ground to wait until the surgeons could reach them. Many were soon beyond the need of surgical assistance. There were four divisions of the army, and each division was supposed to have its hospital. But as a matter of fact there was but one, the division hospital of the fifth army corps, under Major Wood. There were five surgeons, a hospital steward, and twenty assistants to care for the wounded—several hundred. They had a number of operating-tables, a small supply of medicines, but few bandages, and no food for sick or wounded men. It was comparatively easy to get supplies from the *State of Texas* ashore to the hospital here [Siboney], but there was no transportation to get them to the front." In the opinion of the editor of the MEDICAL RECORD and the correspondent of *The Sun*, the Red Cross Society's work was the only redeeming feature of the whole campaign, to judge from the language of the latter: "God knows what we should have done here without the help of the Red Cross, your ships, your surgeons, and your nurses! And there is no other help for us at the pres-

ent. Our wounded up there must have food, bandages, anything you can let us have in the line of hospital supplies."

The editorial in the MEDICAL RECORD brings matters to a focus in the closing sentence: "It is right and proper that the surgeon-general should resent any interference with his prerogatives, but he should not directly invite it by making possible such a condition of affairs as here described." This inference is entirely unwarranted by facts as they existed during and after the battle of Santiago. The correspondent and editorial do not even mention the steamer *Olivette*, which we found, July 7th, anchored close to the shore before Siboney. This steamer, in command of Major Appel, U.S.A., was used as a hospital ship. This ship was in place and ready to receive the wounded during the battle. The steamer, at the time mentioned, had on board three hundred wounded, who received the best surgical attention and nursing. The next day the steamer left for the United States, the medical staff being reinforced by the addition of Acting Assistant Surgeon Brown, of Chicago, from the *Relief*. General Sternberg at an early date recognized the importance of hospital ships during this war. The *Olivette* was chartered for this special purpose, was well equipped, and reached the seat of war in trim. The hospital ship *Relief*, formerly the *John Englis*, under the supervision of its commander, Major Torney, was transformed into an ideal floating hospital in less than six weeks and reached Siboney July 7th, a day before the *Olivette* left for its home port. Do these things show either negligence or ignorance? Do they not rather demonstrate foresight and an earnest endeavor better to care for the sick and wounded in a way creditable to our country and the chief of the medical department?

This question can be safely left for the wounded to answer. The surgeon-general accepted the legitimate services of the Red Cross Society, and had reason to expect aid from this source should pressing contingencies present themselves. The medical officers, the wounded and sick, have every reason to be grateful to Miss Clara Barton for what she did in furnishing ice, delicacies, and medical supplies. The *State of Texas* did excellent work in and with the medical department, but this is no reason why those connected with the Red Cross Society should claim all the credit and undertake to criticise a department of our government which has done all it possibly could in anticipating the requirements of a sudden emergency. It is a source of great regret that there should be any friction whatever between the medical department and the friends and supporters of the Red Cross Society. It must be clear to every unprejudiced mind that the treatment of the sick and wounded must remain under the direct care, control, and management of the medical department, and that the legitimate functions of the Red Cross is rather auxiliary to it than as an independent organization, if the greatest amount of good is to be realized from it. The hospital ship *Relief* brought an immense amount of medical supplies, delicacies, cots, pillows, and blankets. When we arrived at Siboney, we knew our presence was much needed, and looked in vain for some one in power to inform us where and how to land. The precipitous and rocky nature of the shore and the immense depth of the ocean made it impossible to secure anchorage for several days. A single lighter attended to the demands of necessary transport ships. I am sure no one could blame the medical department for the unavoidable delay in unloading the supplies. The little steam launches did what could be done in bringing to the shore what was most needed. Major Torney worked night and day in having the requisitions made by the surgeons in the field and hospitals. There was no red tape here; all they had to do was to inform him what was wanted, and it was delivered as soon as it could be brought to the shore. The lack of proper transportation facilities from the landing to the front cannot be charged to the medical department. It took more than a week of the hardest kind of work to land all of the supplies, and, considering the limited facilities available, it is and always must be regarded as a source of satisfaction that it was made possible at all. The *Relief* brought one thousand cots and an ample supply of blankets, which reached the hospitals with as little delay as possible. Lieutenant Crabbs, of the eighth cavalry, showed a creditable degree of ingenuity, energy, and often of courage in landing the supplies.

The complaint that the sick and wounded lacked medicine and dressing-materials is true only to a certain extent. Some of the medicines were exhausted, owing to the unexpected enormous demand, but they were supplied as quickly as could be done under the existing circumstances. The writer had the privilege of operating in all of the hospitals, and was always able to find the essential antiseptics and dressing-materials required in military practice, and this was at a time when the supplies were at the lowest. There was no lack at any time of stimulants and anæsthetics. There is no use in denying the fact that immediately after the battle the bandage and blanket supplies were inadequate, but these defects were corrected promptly. War always has had its hardships and discomforts; it cannot be prosecuted in parlor cars and clubhouses. Our soldiers expected deprivation and unavoidable discomforts, but on the whole they were subjected to less actual suffering than they had reason to look for. To the credit of the medical officers it must be said that they shared the unavoidable hardships with the soldiers. They lived on the same food, drank the same water, and made the moist ground their bed. The writer will always cherish the memory of the hardships incident to the campaign in a foreign country, a tropical climate, and among a strange people. The Cuban campaign was planned and executed so quickly that some omissions and defects had to be expected. It is a source of gratification to know that the complaints made against the medical department have come from newspaper correspondents and camp followers, more than from the soldiers themselves. Among the thousands of sick and wounded with whom I have been brought in contact during the Cuban campaign, I have seldom heard of a complaint; on the contrary, I have heard nothing but words of praise for the hard-working, self-sacrificing medical officers and the department they represent in the field.

LIEUT.-COL. N. SENN, U.S.V.,
Chief of the Operating Staff with the Army in the Field.

ON BOARD THE HOSPITAL SHIP "RELIEF,"
August 3, 1898.

RESTRICTIONS OF MEDICAL PRACTICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial with this title in a recent issue impels me to overcome my reticence and voice an opinion, even if it is an heretical one. So sincere am I in my convictions that I have the temerity to seek your columns, even at the risk of inviting the animadversions of interested parties.

It is my experience that legislative interference in any legitimate pursuit is detrimental to that pursuit and in a profession it brings about the opposite of what is intended. It legitimizes superficiality and hoodwinks the public; it creates spurious physicians to the everlasting detriment of the genuine and of the public as well.

As for restrictions, where and what are they? Will

any one deny that the acquisition of a medical diploma is an easy task and not restricted to the schooled, either in learning or in morals? The question of fitness never arises, and all who apply at the right door may enter. And what of those who gained access to the public by other means?

Are the glaring signs of "positive cures" ever disturbed? Are the brazen advertisements of charlatans ever challenged? Are the questionable schools of medicine ever fought in any other way than in politics and medical journals?

Is it not a fact that the number of medical colleges is rapidly increasing? Is it not a fact that the percentage of practitioners is steadily rising? Is it not a fact that the medical profession is yearly becoming more heterogeneous? Is it not a fact that quacks are steadily increasing, both as to numbers and kinds? Is it not a fact that competition is ever becoming keener and not limited to individuals, but includes charitable and private institutions, hospitals, boards of health, societies, patent-medicine venders, medical colleges, etc.?

Mr. Editor, pray what are the significance and logic of the word "restrictions"?

E. GOODMAN, M.D.

SAN FRANCISCO, July 17, 1897.

[It is possible that the conditions to which our correspondent refers still prevail in certain parts of the country, but they certainly do not in all. The general tendency is now to the consolidation of existing medical colleges rather than to the creation of new ones, the curriculum in the colleges is being lengthened, and the standard of medical education throughout the country is steadily being raised. In the States which have efficient medical laws, and they are in the majority, the question of fitness does arise, and by no means all who apply can enter, as the statistics of the various medical examining-boards attest. Dr. Goodman writes as one from the past, and many if not most of the evils of which he complains have gone into history.—ED.]

A MEDICAL TRIP TO EUROPE—WHY NOT TO HOLLAND?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: With great interest I have read in your columns the correspondence of Dr. J. Preston Miller, entitled "The Different Fields of Operative Surgery and Gynæcology in Europe." For us who were born and live in the old world, it is always interesting to hear the remarks and benevolent criticism of those of your countrymen who come over the great ocean to see through their own eyes what is worthy to be seen. This is especially so in medicine, for this science is international, perhaps more so than any other science, and the younger generation of medical men in Europe should not think themselves sufficiently equipped for practice before having visited at least a number of the clinics and hospitals seen by your correspondent. So what he tells of the personal qualities and peculiarities of the leading surgeons and gynæcologists will be appreciated also by your European readers.

But there are those of one nation who were disappointed in reading the letters, and you will permit me to express my regret, when following your correspondent to Brussels, to see him taking route to London, without giving at least a glance at the old country of the Pilgrim Fathers. Had he done so, he might have seen that the Dutch doctor, as well as his quoted Brussels confrère, is accustomed to speak the modern languages—English, French, and German—for, because of the comparative smallness of his country, his education must be distinctly cosmopolitan; and I venture to say (with becoming modesty) that the Dutch teachers and operators do not deserve to have been passed over by your correspondent.

He might have gone to Amsterdam, a city with a population of about half a million, where much valuable material (if you do not partake of my objection to calling men material) is to be seen in the city hospital, which is almost entirely at the disposal of the clinical professors of the university. He could have seen the brilliant operations performed by Professor Treub in gynæcology and by Profs. Korteweg and Rotgans in surgery; he could have admired the diagnostic skill of Professor Pel; he could have heard the eloquence of Stohris; he could have taken a look at the polyclinic of Guye, of aprosenia fame.

He might have visited the old university of Leyden, and perhaps been rejoiced by the surgical genius of Iterson, or by the clinical instruction of the renowned Rosenstein.

Had he paid a visit to Utrecht, he might have deplored the sudden death of Halbertsma, whose theory on eclampsia puerperalis will not be utterly unknown to him; and he might have admired the ophthalmological institute of Snellen, the worthy successor of the world-famed Donders.

Even in the northern part of our country, at Groningen, he might have found a university with able professors, and might have enjoyed the didactic ability of Nyhoff in obstetrics and gynæcology. In returning to America he could have reached London from Rotterdam, and could have visited in this and other towns the municipal or private institutions, in some of which, called "Diaconessenhuisen" (deaconesses' hospitals), he might have seen the most heroic operations in general and gynæcological surgery.

In finishing, I wish to express the hope that some other occasional reporter of the leading medical paper of the United States may pay a visit to Holland, and follow the example of your countryman, Dr. J. A. Otte, now a medical missionary in Amoy (China) of the Dutch Reformed Church in America, who spent some months at the different medical and surgical clinics in Holland before settling in China, and who often told me he was very glad to have seen so much interesting work in Holland.

W. B. VAN STAVEREN, M.D.

ROTTERDAM, July 19, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 30, 1898:

	Cases.	Deaths.
Tuberculosis	200	157
Typhoid fever	28	8
Scarlet fever	99	15
Measles	94	8
Diphtheria	152	16
Laryngeal diphtheria (croup)	2	2
Cerebro-spinal meningitis	0	7
Chicken-pox	4	0

Pruritus Opii.—Dr. John H. Billings, of New York, writes: "Regarding the mention made of this in a recent issue of the MEDICAL RECORD, I have observed that in this condition the pruritus is largely of the scrotum and end of the nose, more particularly the latter. In one case the injection of one-eighth of a grain of morphine hypodermically, given to relieve abdominal pain, caused the most intense itching of the cutaneous covering of the scrotum. The patient being under observation for upward of a week, this symptom was observed on each exhibition of the drug."

THE RESULTS OBTAINED BY THE OPERATION OF PARTIAL THYROIDECTOMY IN EIGHT CASES OF GRAVES' DISEASE.[1]

BY J. ARTHUR BOOTH, M.D.,

NEW YORK.

In a paper entitled "The Thyroid Theory in Graves' Disease," read before this association on May 30, 1894, the writer reported two cases of this disease, whose condition had been much improved by the removal of one lobe of the thyroid gland. Since then six others have received the same form of treatment, and I think the present time and opportunity advantageous for the impartial and candid consideration of the facts herein given, in order that, by comparing the conditions now present with those existing prior to the surgical treatment, we may arrive at some definite conclusion as to the advisability of asking the surgeon's aid for the relief of the trying symptoms present in this disease. I confess that the results obtained from medical, hygienic, and other measures have been discouraging in a large number of patients, even in those who were able by their circumstances to take advantage of all that these different departments of medicine offered. When, however, one from a lower station in life, dependent on her daily labor for support, applies for relief, we feel indeed handicapped and usually fail in our efforts in removing not only the objective but also the many nervous symptoms from which these patients suffer. It was in consideration of the latter class and the introduction of the thyroid theory that prompted me to a trial of more radical measures, and though the results are not entirely satisfactory, still I can justly claim they are better than those obtained by me with other methods of treatment. The operation consisted in a removal of one lobe of the thyroid gland, and was performed by my friend, Dr. B. F. Curtis.

CASE I.—The patient, Louise E——, aged twenty-four years, was first seen January 23, 1893. The family history is entirely negative. She never had any illness worthy of note up to the date of the present trouble. About two years ago she first noticed enlargement of the neck, and three months later the eyes became affected. The patient is positive that there were no heart symptoms until six months later, when palpitation, throbbing in the vessels of the neck, shortness of breath, and flushing of the face appeared. All these symptoms gradually increased in severity, and in addition there was marked insomnia, because of the tumultuous action of the heart. Both eyes are very prominent, especially the left, and the lids do not follow the movements of the eyeballs. The pupils are moderately dilated, reacting to light and accommodation. Vision not impaired and fundus normal.

The enlargement of the thyroid is marked, the right lobe being the larger. On inspection, pulsation is quite noticeable over this region along the sides of the neck. Over the middle of the thyroid the neck measures fourteen inches. The pulse is 150 and of high tension. The apex beat is diffused but no murmur is present. Respirations, 24 to the minute. Measurement over bust thirty-one and one-half inches, and on full inspiration thirty-two and one-fourth inches. During a period of six months, from January to July, 1893, the patient received daily applications of galvanism and appropriate internal medication. At the end of the above period there was some improvement in all the symptoms, including a slight reduction in the size of the neck, and the eyes were less prominent. During July, August, and September, the patient received no regular treatment, but faithfully carried out my instructions as to resting several hours each day. After this time she relapsed into her former condition; the exophthalmos was well marked, and the right lobe of the thyroid very prominent. Further treament failed to make any material alteration in her appearance, or to cure the many subjective symptoms from which she suffered; so operative interference was considered and decided upon.

FIG. 1.—Case I.

The operation was performed by Dr. B. F. Curtis on November 11, 1893. A right transverse incision was made just below the hyoid bone and a vertical incision from the inner end of this at the median line. The flap thus made was turned back and exposed the right lobe of the thyroid. There was but little bleeding, the vessels being carefully dissected out and tied as found. A supernumerary lobe was found attached to the inferior angle and pressing directly upon the trachea; this was removed. The entire exposed mass was then separated from its bed and from the trachea, the isthmus ligated, and the whole right lobe removed.

During the operation the pulse was between 180 and 200, irregular and intermittent, but respiration continued normal and no stimulation was necessary. By evening she had made a good recovery from the ether, complaining of severe pain in the throat. Voice

[1] Read before the American Neurological Association, May 26, 1898.

not husky and of good strength. Up to the fourth day after the operation, nothing occurred worthy of note; the patient then had much nausea and vomiting, accompanied by a sharp rise in temperature. These symptoms continued for two days and then rapidly disappeared. On the tenth day the dressing was removed for the first time, and the wound was found healed by primary union.

The course of the case after this was satisfactory, and on the sixteenth day she was discharged from the hospital.

Inspection of the specimen after removal did not reveal any great degree of vascularity; it was homogeneous in appearance and hard in consistence. Microscopically, the tissue showed the structure of normal thyroid gland with the alveoli moderately dis-

Fig. 2.—Case II.

tended with hyaline material, and in places thickly crowded small cells, both in the alveoli and in the stroma, but principally in the latter.

May 30, 1894, seven months since the operation, there has been a progressive and decided improvement in all the symptoms; especially is this so with regard to the various nervous phenomena, viz., insomnia, restlessness, flushing of the face, excessive sweating, and palpitation. The eyes are less prominent, and the pulse now varies between 96 and 110, as compared to the former ratio of 120 to 160. The appended table shows the pulse average of the past nine months.

Average of Pulse Rate.

August, 1893	148
September, 1893	156
October, 1893	136
November, 1893	146
December, 1893	120
January, 1894	120
February, 1894	110
March, 1894	104
April, 1894	104

For the past four years she has been employed in one of the large department stores, being on her feet most of the time from eight o'clock in the morning until six at night, not missing a day from her work, and during this period she has not been disturbed by any of her former symptoms. The patient was examined on May 10, 1898, and the following notes were recorded: Eyes still prominent, but the wide, staring expression is absent. No palpitation or dyspnœa. The pulse is 90 after a rapid walk of six blocks to the office. The patient is perfectly satisfied with her present condition and considers herself cured.

Case II.—Anna D——, aged twenty years, single; seen April 23, 1893. Three years before she noticed enlargement of the neck and three months later a prominence of both eyes. She became very nervous, could not sleep, and was very much disturbed by frequent attacks of palpitation. The right lobe of the thyroid was removed on May 11, 1893. Marked improvement in all the symptoms followed. One year after the operation there was entire absence of any exophthalmos; the pulse, formerly 140, was down to 100, and the nervousness had disappeared. When seen on April 24th last, she said she was perfectly able to perform her household duties without any fatigue or palpitation and was feeling entirely well. The pulse was 80 beats to the minute and the eyes were normal.

Case III.—Nettie D——, aged forty-two years, single, was seen June 22, 1894, and the following history obtained: Twelve years ago the patient received a severe fright, the nature of which she will not give. She was very much prostrated and became very nervous. Six months later she noticed a bunch on the right side of the neck, which gradually increased in size and finally extended over to the other side. Two years ago she became very much annoyed by frequent attacks of palpitation and shortness of breath after slight exertion, also by a throbbing in the vessels of the neck. Within the last year the eyes have become very prominent, and this condition is well shown in the accompanying photograph. Recently she has passed large quantities of urine and has been under treatment for diabetes.

Examination revealed all the symptoms of the disease to an extreme degree. She was admitted to St. Luke's Hospital on September 24, 1894, and, no kidney complications being found, the operation of par-

Fig. 3.—Case III.

tial thyroidectomy was performed by Dr. Curtis on October 1, 1894. Shortly after the effects of the ether had passed off there developed a high degree of fever; the patient rapidly passed into a comatose condition and finally died twenty-four hours after the operation. An examination of the urine revealed a large percentage of albumin, hyaline and granular casts. No autopsy was made and therefore it is difficult to arrive at any conclusion as to the real cause of death; but from the examination of the urine and the symptoms it is probable that the final condition was one of uræmia and not to be explained by the sudden absorption of an excess of the secretion of the thyroid gland.

Case IV.—Nellie C——, aged seventeen years, single; seen November 5, 1895. When six years old a

sister, taking her in her arms, made a pretence of throwing her out of the window. She was very much frightened, and an attack of what was called brain fever followed. She was confined to the bed for several months, and during this time had a number of convulsions, but finally made a good recovery. She remained well until the appearance of menstruation six years later: about this time, when thirteen years

Fig. 4.—Case IV

old, a swelling of the upper lids of both eyes was noticed, which has gradually increased and now has become so noticeable as at once to attract attention. This symptom is more marked in winter than in summer.

She now complains of frequent attacks of palpitation of the heart, accompanied by throbbing in the neck and profuse perspiration; also of general nervousness and occasional headache. She has never noticed any prominence of eyes, enlargement of the neck, or swelling of the hands or feet. On examination the patient presents the appearance of a case of Graves' disease. When we examine the eyes, however, no exophthalmos is discovered, but instead a very marked and peculiar œdema of both upper lids, as is shown in the accompanying illustration. It is not a true œdema; no pitting follows pressure and it does not cause the closure of the lids, such as is produced by ordinary œdema. Movements of the eyes and lids are harmonious. On inspection there is no decided prominence of the thyroid gland, but on palpation swelling and a diffused hardness of both lobes are made out. The heart action is agitated and pulse rate rapid, averaging 120 beats to the minute. With the exception of loud hæmic murmurs at the base, the heart is normal. Face, neck, and both hands are covered with beads of perspiration. There is a slight tremor of the fingers.

One month later (December 5th) prominence of the left eye appeared. Having been unable to do any work for some time, even to attending to minor household duties, the patient willingly consented to operative interference, and on December 15th she was admitted to St. Luke's Hospital, where a few days later the right lobe of the thyroid was removed by Dr. B. F. Curtis. Her recovery from the effects of the operation was rapid and the progress of the case up to the present time has been entirely satisfactory. It is now two and one-half years since the operation, and during this time there has been a complete disappearance of all nervousness; the throbbing and palpitation have ceased, and with two exceptions the pulse has not been above 90, most of the time varying between 80 and 86; no exophthalmos. Although the improvement in the symptoms just mentioned has been marked, the peculiar œdematous swelling of the eyelids still persists.

Case V.—Amelia B——, aged twenty-one years, single, domestic; seen with Dr. Curtis November 29, 1895. Present trouble began four months before, when she felt a movable, painful swelling, about the size of a cherry, on the left side of the throat, which caused her pain on swallowing or talking. About a month later it had grown to about the size of a pigeon's egg and was quite visible. She became very nervous, could not sleep, and had attacks of palpitation. Examination did not reveal any prominence of the eyes. Pulse rate, 110 and irregular.

The left lobe of the thyroid gland was removed; the patient made a good recovery from the operation and was discharged from the hospital on December 2d, entirely relieved of the pressure symptoms from which she suffered. Three months later the nervous symptoms had disappeared, the pulse became normal, and when seen on May 18th last she was perfectly well, the pulse being 74; no nervousness or insomnia.

Case VI.—Addie T——, aged thirty-five, married. This patient was referred to me by Dr. Curtis on January 10, 1896. Her general health was good up to ten years ago; then she first noticed a swelling on the left side of the neck, which gradually increased in size. Palpitation of the heart and general nervousness appeared five years later. At no time had she noticed prominence of the eyes. Examination revealed a decided enlargement of the left lobe of the thyroid, throbbing along the vessels of the neck, and a pulse of 120. The eyes appear normal both in size and movement.

Fig. 5.—Case VII

One year ago her sister died with symptoms of the disease, and now another sister has the same trouble.

On January 11, 1896, partial thyroidectomy was performed by Dr. Curtis, the left lobe being removed. No shock followed, and she made an uneventful recovery from the operation. For the past year she has been entirely free from any marked nervous symptoms

and has had no tachycardia. The pulse now averages about eighty beats to the minute.

Case VII.—Mabel B——, aged twenty years, single. Patient first seen November 20, 1896. Enlargement of neck noticed one year previous, followed by general nervousness, tremor of hands, excessive sweating, attacks of palpitation and dyspnœa. Pulse rate very rapid—160 to 180. Has had frequent attacks of diarrhœa. Exophthalmos slight. After six months' rest in bed, and having received no benefit from either this or many therapeutic measures, she was prepared for operation, and on June 28th thyroidectomy was performed by Dr. Curtis, the entire right lobe being removed. She returned home on the 19th of February, 1897, unimproved. It is now a little over a year since the operation, and there does not seem to be any decided improvement in her condition, though she states that palpitation and throbbing are less. Before, she was disturbed four or five times at night by attacks of smothering and palpitation; she now sleeps undisturbed by any such symptoms. The tremor is still present, but not so marked. The pulse rate is now 120; formerly 140 to 180.

Case VIII.—Mary M——, aged thirty-six years, single; bookkeeper. Patient referred to me by Dr. David Webster on October 12, 1897. Onset of symptoms one year previous, consisting of general nervousness, prominence of eyes, rapid pulse—128–130, tremor of hands, and enlargement of neck. Admitted to St. Luke's Hospital on October 28th, and on November 13, 1897, the right lobe of the thyroid excised by Dr. Curtis. Her recovery from the effects of the operation was uneventful, and she returned to her occupation as bookkeeper in five weeks, feeling better. When seen on April 26th last she stated she had been very much improved in every way. She is less nervous, sleeps as well as ever. She is now able to write and keep her books neat; formerly she was not able to do this on account of the tremor of the hands, which was so marked as to resemble that of chronic alcoholism. She has hardly any palpitation now, and the pulse varies from 90 to 100. Prominence of eyes hardly noticeable.

Summary.—It will be seen from the preceding that the operation cured five of the eight patients. One died; in one no change has occurred; one has been improved, and in this case it is worthy of notice that the operation was performed only six months ago, so that we may expect still further improvement and perhaps a cure; for the longer the period of observation after operation the better appear the results. The order of improvement in my cases corresponds with that observed by others; first the goitre diminishes, next the nervous symptoms disappear, then the pulse rate and vasomotor phenomena improve, and the exophthalmos last of all.

Surgical intervention in Graves' disease has been espoused in the works of Stierling, Heidenreich, Lemke, Kocher, Buschan, Solary, and others, all reporting successful results in a number of cases. Solary in 69 observations reports 84 per cent. improved. Heidenreich in 61 cases had 50 cures and 5 failures. Buschan gives the following statistics: 80 cases—31 cured, 20 improved, 6 deaths, 16 failures, 7 unknown results. Mikulicz in 11 cases had 7 patients fully cured, and 4 essentially improved. Besides these, numerous other authors report cases cured or improved by operative measures.

The following is a list of fatal cases after partial thyroidectomy from 1890 to May 1, 1898: 1892, Lemke, 1; 1893, Cohen, 1; 1893, Wolff, 1; 1896, Mattieson, 2; 1896, Riedel, 5; 1897, Embden, 1; 1897, Lejard, 1; 1897, Wiesinger, 1; making 13 in all for this period. The deaths take place suddenly, either at the time of the operation or soon afterward, and the rapid onset of the acute symptoms, with death following in a few hours, has caused much speculation as to their cause.

Conclusions.—(1) Cases of Graves' disease may be entirely cured by operative measures. (2) Pathological and clinical evidence is in support of the view that the symptom complex is the expression of a primary neurosis multiplied by a secondary glandular intoxication. (3) While the ultimate cause of the disease of the gland is still a matter of speculation and a mortality of seven per cent. after operation is reported, we cannot justly recommend it as a routine plan of treatment. (4) Sudden death may occur in the course of or soon after operation, and has not as yet received a satisfactory explanation.

MOVABLE KIDNEY AND ITS TREATMENT.

By MAX EINHORN, M.D.,

NEW YORK.

While from an anatomical point of view movable or floating kidney was already known in the middle ages, its clinical significance was not recognized until this century, and has been fully appreciated only in the last fifteen or twenty years. In the following I have taken the liberty to present a brief historical review of this subject and to supplement this with the results of my personal experiences.

Rayer[1] was the first to make the diagnosis of floating kidney, as early as the year 1836, and has given an accurate description of this condition. In his celebrated work upon kidney diseases, vol. iii., page 783, this author writes as follows: "The movability of the kidneys, or that condition which admits of their sagging down, or slipping forward, or shifting backward or upward beneath the liver, is a cause of various occurrences, especially of frequent pains in the abdomen and in the corresponding leg—pains which have often been regarded as nervous colics, as symptoms of hypochondriasis, and occasionally even as lumbar neuralgias."

Rayer reports eleven cases of movable kidneys which he observed himself, and formulates the results of his experiences as follows: "In *résumé*, the movability of the kidneys constitutes a morbid condition which has been but little studied, and occurs much more frequently than is commonly assumed. The right kidney comprises almost exclusively the site of this anomaly; it is found much oftener in women than in men. Quite frequently it occurs in connection with an enlargement of the liver, with a displacement of the intestine, or with a prolapse of the uterus. It may result from a special disposition of the peritoneum, a deviation of the kidney, or the greater extensibility of the vessels, etc. Repeated pregnancies, exertion in carrying or lifting heavy burdens, appear in some cases to be the cause of this dislocation of the right kidney; in other cases, however, an explanation of this anomaly is lacking. The pain in the right lumbar region, which sometimes radiates in the direction of the lumbar and crural nerves—a pain which can be evoked in a condition of rest by pressing with the fingers of the right hand upon the right kidney, while the left hand supports the lumbar region behind—and a constant feeling of weakness and discomfort in the lower portion of the abdomen, are the most frequent symptoms of this disease."

In reference to the treatment, Rayer has already presented the most essential points. He says: "Experience has shown me that most commonly it is sufficient to support the abdomen by means of a properly applied bandage, in order to cause the disappearance of the pain due to the movable right kidney, or at least to render it more endurable."

The next important work on this subject is by

Charles J. Hare,[2] and appeared in 1858—that is, just forty years ago. I venture to cite the following remarks: "This 'movable condition of the kidneys,' though not very common, is yet, I feel convinced, much more so than is generally supposed, and is, at any rate, not so rare but instances of it must present themselves occasionally to most medical men who are engaged in extensive practice. I shall subsequently give you further particulars as to the relative frequency of this affection in the two sexes, etc., but I may mention here that it occurs very much more commonly among females than among males, and that mobility of the right kidney is much oftener met with than of the left, while, if the two organs be affected, the right is usually the more so. The habitual position of a mobile kidney is almost always lower than natural, but it varies notably according to whether the patient be in the recumbent or in the upright position, being lower, of course, in the latter; even when the patient lies on the back (if the abdominal parietes are moderately flaccid and not too fat), the lower end or perhaps even the greater part of the kidney may be felt below the costal cartilages."

Bimanual palpation is described by Hare as follows: "Suppose the right side is to be examined; the patient being laid on the back, with a slight inclination toward the right side, the head and shoulders being raised and the legs somewhat elevated, the observer should stand or sit to the right of the couch but somewhat facing the patient, and should place the fingers of the left hand on the postero-lumbar region, immediately under the last rib, at the same time gently pressing or pushing forward that part. The ends of the fingers of the right hand should then be placed in front, just below the costal cartilages, and there also a slight pressure should be exerted. The lower end of the kidney will thus probably be felt between the two hands. The patient should next be told to take a deep inspiration, and then to expire slowly; the observer should in the mean while keep his hands in the same position as before, but, just at the commencement of expiration, should press the fingers of the right hand rather sharply down toward the renal region. He will probably detect a much larger portion of the kidney between the hands than previously; it has been detruded downward by the action of the diaphragm. Sometimes the kidney may thus be retained between the hands, and now and then it may be detruded much lower into the abdomen, but it usually slips away from between the fingers, and is lost for a moment under the liver or in the proper renal region. In other cases, when the mobility is greater, if at the moment of commencing expiration (after a deep inspiration) the right hand be pressed edgewise along the margin of the costal cartilages, and sharply downward toward the renal region, the kidney will very probably glide or slip downward, so that the whole of it will be below the hand—below, that is, the level of the position where its inferior border is usually situated. In other instances, without this manipulation, the kidney is felt as a body so movable that it can be taken up, as it were, through the parietes, and be shifted or pushed to different parts of its own side of the abdomen, or even moved to the front of the spine. The degree of mobility, therefore, varies very much in different cases; it may amount to but a slight departure from the usual tolerably fixed condition of these organs, while, on the other hand, I have met with a case in which the right kidney could readily be moved upward and downward, over a space of between four and five inches, and to a considerable extent transversely across the right half of the abdomen."

Hare observed twenty-three cases, twenty in women and three in men. For the treatment of movable kidneys he recommends chalybeates, regulation of the bowels, avoidance of much standing, horseback exercise, and the wearing of a proper elastic abdominal bandage, and continues as follows: "But the greatest and most efficient relief is obtained from the use of an elastic abdominal support, provided this be made so as to fit thoroughly well; if not, it sometimes aggravates rather than relieves the pain; and one difficulty lies in preventing its slipping too high up on the abdomen, when it acts somewhat like a belt round the waist, and may even tend to detrude the kidney downward."

After quite a long lapse in the study of movable kidneys, there appeared several articles upon the surgical treatment of this affection. Thus Keppler[3] suggested extirpation of the organ as the only possible cure of floating kidney. This author states in his work that "floating kidney, *per se*, even when unattended with any complication whatsoever, should be removed by nephrectomy by means of abdominal incision, as soon as it causes any perceptible disturbances in the organism." This suggestion has, as a matter of fact, been frequently carried out, and from a tabulation by Sulzer[4] it appears that among 37 nephrectomies which were undertaken for the cure of floating kidneys there were 26 cures, 1 failure, and 10 deaths —a mortality of 27 per cent.

It may be readily understood that soon voices were raised against this severe and dangerous procedure, and E. Hahn[5] was the first to propose the fixation of the kidney, or nephrorrhaphy, for the cure of movable kidney, an operation which has been often performed by this surgeon and, following him, by many others. According to the compilation of Sulzer, the results of fixation of the kidneys were 93 successes, 4 improvements, and 15 failures—that is almost one-third; among 80 cases of nephrorrhaphy, 2 terminated fatally.

In this country Edebohls[6] has perfected the technique of nephrorrhaphy, and performed this operation fifty times, in the period of 1890 to 1895, with but one death. Landau,[7] one of the best diagnosticians of floating kidney, expresses himself as opposed to any operative interference in this affection.

Our knowledge of movable kidney or floating kidney was immensely enlarged by Glénard's[8] masterly work. This author recognized that it is not the kidney alone which is displaced downward, but that in connection with it several other abdominal organs become looser or more movable, and descend more or less. The "ren mobilis" is, according to him, one of the concomitant appearances of enteroptosis: that is, a descent of the stomach, intestine, and other abdominal organs. For the recognition of movable kidney, which, so to speak, forms one of the chief symptoms of enteroptosis, Glénard justly places full weight upon bimanual palpation, which was originated by Hare, as appears from the above description. To Glénard, however, belongs the credit of having laid the foundation of our knowledge of enteroptosis and having promulgated the same in the medical world. Coincidentally with the advances made in the study of enteroptosis, the study of floating kidney was more widely diffused and appreciated. Ewald,[9] and, following him, Kuttner,[10] Bial,[11] and Huber,[12] in Germany, have made instructive contributions to our knowledge of this affection. Here, in this country, I [13] published, in 1891 and 1895, some observations upon this subject. The surgical treatment of floating kidney has now, and with justice, been relegated to the background; for, as this condition is only one of the concomitant appearances of enteroptosis, very little benefit is derived, as a matter of fact, from a nephrorrhaphy.

In the last eight or nine years I have had an opportunity of observing nearly five hundred cases of movable kidneys, and I take the liberty in the following to describe this anomaly on the basis of my personal experiences.

Definition.—By the term "movable kidney" or

"floating kidney" is understood a condition in which the kidney is more or less accessible to palpation.

According to Landau, the kidneys are situated normally in the posterior region of the upper abdomen, and in part within the bony walls of the thorax, at the sides of the transverse processes of the vertebræ, the inner margin being at an average distance of 7.5 cm. from the median line. They extend laterally from the lower border of the eleventh dorsal vertebra to the lower border of the second lumbar vertebra; they are inaccessible to palpation.

According to Glénard, four different degrees of mobility of the kidneys can be distinguished, viz.:

First degree of nephroptosis:* The lower part of the kidney can be felt during deep inspiration, while during expiration the organ returns to its place, and it is not possible to hold it securely.

Second degree: The greater portion of the kidney can be palpated and can be held firmly, but the upper border cannot be felt.

Third degree: During deep expiration the upper border of the kidney can also be reached.

Fourth degree: The entire kidney is accessible to palpation, even during expiration (the movable or floating kidney of authors).

A congenital floating kidney is covered with peritoneum, and is of rare occurrence; clinically it cannot be differentiated from the acquired movable kidney.

Etiology.—Movable kidney occurs more frequently upon the right than upon the left side. Occasionally both kidneys are movable, although it is extremely rare to find the left alone movable. This anomaly occurs much more frequently in women than in men. The statistics regarding the frequency of floating kidney differ in the writings of the older and of the more recent authors. Senator,[15] as late as 1883, computed one floating kidney to about one hundred and seventy-one women. On the other hand, Glénard found this anomaly in one out of every four women: Lindner[16] noted a similar proportion, namely, one floating kidney in every five or six women. This great divergence may be explained on the ground that since Glénard's publications the examinations for floating kidneys have been more frequently instituted and more critically (bimanually), so that the more recent authors can furnish more careful statistical material. The proportion of frequency among men and women is clearly represented by the statistics of Kuttner. This author has examined 100 cases of palpable kidneys, comprising 94 in women and 6 in men. Kuttner has also investigated the position of the stomach in 89 of his cases of floating kidney, and found it normal in 10 instances; that is, the stomach was situated above the umbilicus; while in the remaining 79 the greater curvature was situated two or three fingers' breadth below the navel.

Hilbert[17] has examined 100 cases of movable kidneys in women, in 65 of which the right kidney alone could be felt, in 35 both kidneys. Among the cases in which the right kidney only was palpable, 40 presented the first degree and 25 the second degree of mobility. The first degree of mobility of both kidneys was observed by him in 8 instances; the second degree in 9. A true floating kidney was noted by him only once among 100 cases, and then in connection with a palpable kidney on the left side. Among these cases Hilbert never met with a left palpable kidney. Disturbances could be referred to this anomaly only in 15 per cent. of the cases.

In order to gain exact information regarding the frequency of floating kidney in men and women, I have reviewed the cases recorded in my private notebook since 1897, especially those affected with digestive disturbances. Altogether, 1,315 patients are recorded, comprising 772 men and 543 women.

Among the 772 male patients 14 were affected with floating kidneys, all on the right side. As expressed in percentage, the proportion of movable kidneys was 1.81 per cent.

Among the 543 female patients, 112 presented floating kidneys—107 being on the right side, 4 on both sides, and 1 on the left side. The frequency of movable kidneys in some female patients, therefore, amounts to 20.6 per cent.

As regards the degree of renal mobility, among the 14 cases of floating kidneys in the male sex 4 were in the first and second degrees, and 10 in the third and fourth degrees. Among the 112 cases of women, 32 were in the first and second degree, 70 in the third, and 10 in the fourth degree.

In about one-third of the cases of floating kidneys of both sexes, a marked gastroptosis (the stomach usually lying between the navel and symphysis) was present; while in the majority of the other cases the greater curvature reached as far as the umbilicus, or from one to two fingers' breadth beneath; coincidentally, the transverse colon was, of course, displaced farther downward.

Among the 112 women affected with floating kidneys, 5 presented ptosis of the liver and 1 a ptosis of the spleen. The uterus was also often found displaced downward, although all the cases were not examined with reference to this point, and hence I am unable to furnish exact figures.

If, as we have seen, floating kidney almost always occurs in conjunction with a ptosis of other abdominal organs, it is of interest to learn whether ptosis of the abdominal viscera may take place without floating kidney. Inasmuch as gastroptosis is most readily recognized, and, moreover, is always a characteristic feature of enteroptosis, I have since 1897 examined those of my patients unaffected with floating kidneys with reference to this point, and have determined a marked descent of the stomach in fourteen women and two men, among these being two females who at the same time presented marked degrees of hepatoptosis. Hence cases of enteroptosis (gastroptosis) also occur without the presence of movable kidney.

Cause.—The corset is frequently considered as the etiological factor in the occurrence of floating kidney, and even Cruveilhier[18] said: "I have several times noted in women who wear the corset tightly laced, the right kidney in the iliac fossa of that side. This displacement of the kidney arises when, in consequence of the pressure exerted by the corset upon the liver, the right kidney is dislodged from the position which it occupies at the inferior surface of that organ, somewhat like a kernel pressed between the fingers."

Witthauer[19] and Sulzer also seem to hold the corset responsible for the development of floating kidney. According to Sulzer, a much more dangerous agent than the corset in women and girls of the lower classes is the tightly laced waistbands of their dresses, which produce a more or less deep furrow, upon which rests the weight of all the clothing. This pressure crowds the intestines and kidneys downward.

Landau and Senator lay great stress upon previous childbirths as an etiological factor. Sulzer coincides in this, and explains it as follows: "Normally, in the presence of tense abdominal walls, the intra-abdominal pressure aids in holding the kidneys in position against the posterior wall of the abdomen. After delivery, when this condition is no longer active, and when on assuming the upright posture a prolapse of the digestive organs takes place, the kidneys tend much more readily to leave their normal situation, and, as a result of severe labor, or from pressure, straining, etc., may be dislocated downward." At the conclusion

* Israel[14] considers the first degree as still within the domain of the physiological limit of kidney mobility.

of his work, Senator expresses himself as follows regarding the etiology of floating kidneys: "The three named etiological factors—the relaxation of the abdominal walls, displacements of the sexual organs, and tight lacing of the upper abdominal region—appear to me as the most important causes for the development of renal descent, and also explain its great predominance in women."

Rapid emaciation has been regarded, and with justice, as a cause of renal dislocations. Landau says: "One of the most important and frequent causes of mobility is the disappearance of fat in the fatty capsule and the loosening of the peritoneum. Of course, the disappearance of renal fat can become the cause of mobility only when it has been present in large amounts and has been rapidly consumed."

Becquet [20] considers the increased congestion of the kidneys at the time of menstruation as an etiological factor of floating kidneys. The organ becomes heavy and descends, the capsule being stretched and then relaxed, and a dislocation is thus rendered possible.

All the above-mentioned agencies probably play an important part in the origin of floating kidney, but they do not suffice always to explain its occurrence, for sometimes, although rarely, we meet with floating kidneys in young girls (even before the appearance of menstruation) who have not been addicted to the corset or tight lacing and are not emaciated. In males, cases of this kind, in which no cause for the renal dislocation can be determined, are observed even more frequently. I must, therefore, completely coincide with Sulzer's view that it is necessary to assume an individually varying predisposition as regards the degree of fixation of the kidney or its possibility of being displaced. This explanation, of course, applies not only to the kidney, but also to the displacement of other abdominal organs.

Symptomatology.—Movable kidney, as well as enteroptosis, may run its course without any symptoms whatever, and this, indeed, happens quite frequently. On the other hand, cases of floating kidney are encountered which are attended with the most diverse gastric and intestinal affections. In order to describe the pathological appearances of movable kidney, we must not, of course, attribute to the existence of the palpable kidney every morbid phenomenon which a sufferer from this anomaly may present. It will be necessary, therefore, to mention only those symptoms which occur quite frequently in movable kidney and appear to be dependent upon the latter, being removed by appropriate treatment directed to the movability of the kidney (and the ptosis of other abdominal organs).

These symptoms are as follows:

1. A feeling of traction and weight in the abdomen.
2. Quite violent palpitation in the epigastrium (pulsation of the abdominal aorta).
3. The disturbances are usually more pronounced when standing or walking, and disappear on lying down.
4. Frequent urination, occasionally attended with slight burning.
5. Pains in the sacral region after slight exertion.
6. In women the discomfort is usually increased at the time of menstruation, and considerable improvement manifests itself during pregnancy.*

These six symptoms need not always be present; they may all be absent, or occur separately.

Most of the gastric and intestinal symptoms, such as pains, eructations, nausea, occasional vomiting, irregularity of the bowels (chiefly constipation, sometimes diarrhœa), which are present in persons with movable kidney, occur usually independently of the latter, and require therapeutic measures appropriate to such conditions. Gastric neuroses, which originate by reflex action from a movable kidney, are met with, but rarely; among them I would place nervous vomiting and nausea. Whether cases of periodic attacks of continued gastro-succorrhœa can be regarded as reflex symptoms of a movable kidney appears to me doubtful. Of course, these conditions are found in patients suffering from movable kidney, yet I have observed cases in which neither the wearing of an abdominal bandage nor the performance of nephrorrhaphy caused the disappearance of the periodic gastro-succorrhœa.

That floating kidney may be complicated by the most manifold gastric affections, appears clearly from the following summary, which I have taken from my last tables of cases treated by means of intragastric electrization.* According to these, among the 177 cases referred to, 43 were affected with floating kidney; among the latter, 24 suffered from hyperchlorhydria, 10 from chronic gastric catarrh, 2 from achylia gastrica, and 7 from various gastric neuroses (1 case of nervous vomiting and 6 cases of nervous gastralgia). Of course, all other gastric affections (such as ulcer and cancer) may also be present; the latter, however, are not mentioned in the tables, because these diseases are not treated with electricity.

Diagnosis.—The recognition of a movable kidney is quite easy. Palpation is practised bimanually, and differs in no essential respect from the method already described by Hare in the above-cited paper. The hand placed above should not exert too strong pressure, because this may cause a somewhat movable kidney to be forced upward and prevented from gliding downward. When the tumor is felt between the hands, the decision of the question whether it originates in the kidney is not difficult in the majority of cases. Quite frequently the contour of the kidney can be accurately made out by palpation. Occasionally we may be at first in doubt regarding the nature of a tumor situated in the right ileo-cæcal region; whether it is a kidney (movable kidney of the fourth degree) or a distended segment of the ascending colon. If, however, pressure is made upon the tumor, it will be possible, in case it belongs to the colon, to alter its shape (by dislodging the fæcal mass), and now and then a gurgling or other noise will be heard, which is evoked by palpation in the subjacent segment of intestine. A gall bladder filled with calculi is more likely to be confounded with a floating kidney of the first or second degree, but even here the latter can ordinarily be recognized by its shape. Under pressure of the finger, a gall bladder filled with stones sometimes alters its form, owing to the displacement of the latter; yet an error as regards this point may happen to the most experienced diagnostician.

Treatment.—As mentioned above, the use of the abdominal bandage for supporting and lifting up the lower portion of the abdomen had been recommended by Rayer and Hare. This treatment was also adopted by Glénard, and is quite generally recognized. By some surgeons, however, the value of the bandage is questioned. Thus Edebohls says: "In all resources against the condition, it [the bandage] ranks second to nephrorrhaphy; but, in my opinion, it is a poor second." The same author says farther on: "Faithfully as I have tried bandages, however, I must own that I accomplished little good with them." Lewis[21] appears to be of the same opinion. At the conclusion of his article on movable kidney, he says: "The non-surgical treatment has never more than a palliative effect." According to my view, the bandage is a very valuable resource, if we expect from it no more than a

* All these symptoms (1 to 6) may also occur in enteroptosis not complicated with floating kidney; and the treatment of such cases is identical with that of floating kidney.

* These tables may be found in my article, "Nouveaux faits en faveur de l'électrisation intrastomacale." Annales d'électrobiologie, May 15, 1898, p. 319.

relief of the symptoms which result from the abnormal mobility of the kidneys (and other prolapsed abdominal organs). If, however, we expect that this measure will at the same time remove all the existing disturbances (gastric and intestinal affections), we shall meet everywhere with disappointment.

The disturbances of the stomach and intestinal canal must be treated according to the principles prevailing at the present time. It will be necessary first to make an exact diagnosis before recourse can be had to a successful line of treatment.

Besides a serviceable, well-fitting abdominal bandage (a cushion for the kidney can almost always be omitted), the medical treatment consists in promoting the nutrition and strengthening the organism. The former is done by a liberal diet (forced feeding), so that an increase in weight takes place.* The latter is accomplished by gymnastics, by general massage, and electricity. In a few cases, after a considerable increase in flesh has occurred, I have observed not only a disappearance of all the subjective symptoms, but also the return of a previously movable kidney in the second or even third degree to its normal position, so that the organ could no longer be palpated. As regards the special method of kidney massage as operated by Thure-Brandt (Unternier-Zitterdrückung), and warmly recommended by Bachmaier,[22] I have no personal experiences at my disposal, although it appears to me to be unnecessary.

The surgical treatment consisted, first, in extirpation of the kidney, as proposed by Keppler, but this procedure was justly soon discarded. Landau expresses himself as follows in regard to this: "What would one say to the suggestion to amputate a leg on account of sciatica or because of a varicose ulcer, an advice which would be on a par with that here given, namely, to extirpate the kidney?"

Later, nephrorrhaphy was practised. This operation, which was suggested by Hahn, is essentially the same procedure which, although modified in its details (Edebohls, Senn,[23] Reed [24]), is performed at the present time by surgeons.

We now come to the important question: Shall the treatment of movable kidney be surgical or are medical therapeutic measures sufficient? The statements made in the literature regarding this point are widely divergent. On the surgical side, this operation is regarded by some as the only curative measure. Thus, for instance, Edebohls says that the symptoms of movable kidney may be improved by the dorsal posture, the Weir-Mitchell treatment, massage, electricity, and abdominal bandages; all these measures, however, fail in the vast majority of cases, and even the improvement obtained is usually only of transient character. A nephrorrhaphy properly performed in appropriate cases, as demonstrated by his own experience, always brings about improvement and presents a good prospect of a permanent cure. Lewis, who has recently written on this subject, also contends vigorously in favor of operative treatment. On the other hand, Landau is opposed to all surgical intervention, and Huber remarks as follows: "In reference to the therapeutics of enteroptosis, I would emphasize that, up to the present time, I have never been induced, owing to the severity of the symptoms or inefficacy of the adopted non-operative treatment, to refer the patients to the surgeon for the performance of nephrorrhaphy, the most radical treatment which at present still appears admissible. This much can be said, at any rate: that an intelligent application of bandages, in connection with an appropriate dietary and medicinal treatment of the gastric symptoms, will, as a rule, be adequate." Boas[25] also does not appear to be a vigorous supporter of surgical procedures.

My own experiences point decidedly in favor of medical treatment, and for the following reasons:

1. The results of internal dietetic-mechanical treatment are very favorable, if the gastric and intestinal symptoms are treated according to modern methods, if attention is paid to promoting nutrition, and, if necessary, the wearing of an appropriate abdominal bandage is recommended. On reviewing once more the cases of digestive disturbances in connection with floating kidney treated with electricity (electrization was employed on account of the severe gastric symptoms, and not on account of the condition of the kidney), I find that among the above-mentioned 43 patients, 27 were completely cured—that is, all the subjective symptoms disappeared—and 16 were considerably improved. The results were equally favorable in many cases in which electricity was not applied. I refer only to the above cases, however, because I possess accurate data regarding them, and had them for a greater length of time under observation.

2. As is generally known, very many cases of movable kidney are unaccompanied by symptoms. We find a large percentage of digestive disturbances in patients affected with floating kidney, because these ailments afford us the opportunity of examining the patient. If we were to examine all healthy persons, it would soon come to pass that digestive disturbance in subjects of floating kidney perhaps do not occur much more frequently than in those whose kidneys are in a normal position.

These digestive disturbances in the vast majority of cases, therefore, do not depend upon the movable kidney, but upon other general causes; hence an operation upon the kidney would not in the least remove the trouble. Moreover, movable kidney, as already mentioned above, is only one of the manifestations of a general enteroptosis, and suture of the kidney would not remove the ptosis of the other organs.

3. The results of nephrorrhaphy are in no respect better than those of rational medical treatment. As stated above, according to the statistics of Sulzer, the results were unsatisfactory in about one-third of the cases subjected to operative measures; aside from this, there are the risks of the operation, which still has a mortality of two per cent.

In the last few years I have personally had an opportunity of observing three cases in which nephrorrhaphy had been performed by well-known New York surgeons, and in which no improvement whatever occurred after the operation. One of the patients, indeed (Miss M. S——), both of whose kidneys had been sutured, asserted that her ailment had become considerably worse since the operation.

That some surgeons are too quick to undertake the operation is shown by the following case, observed by me during last month:

Miss L. N——, twenty-four years old, came under my observation May 12, 1898. For three years she had suffered from pains in the region of the stomach, which were especially intense about one hour after eating. The appetite is good, but, owing to dread of pain, the patient eats at present but little, and only the lightest food. Bowels are regular and urine is normal. The patient reported that about six weeks ago she had consulted a distinguished surgeon of this city on account of her ailment. This gentleman found a floating kidney on the right side, and explained to her that an operation was necessary. A nephrorrhaphy was then performed, but when, after three weeks' stay in bed, the patient got up, her old disturbances returned with the same severity as formerly. Examination of the thoracic organs showed nothing abnormal. On examination of the abdomen, however, it was found

* More detailed information on this subject can be found in my article, "The Diet of Dyspeptics," MEDICAL RECORD, January 1, 1898.

that the greater curvature of the stomach was situated one or two fingers' breadth beneath the umbilicus. At no place was there any particular tenderness to pressure present. In the right posterior upper lumbar region a scar left after the nephrorrhaphy was observed.

On May 14, 1898, an examination of the stomach contents one hour after the test breakfast showed: HCl +; acidity = 78; free HCl = 48.

On May 16th the stomach was examined in the fasting state, and was found empty. A diagnosis of hyperchlorhydria was made, and the patient was directed to take frequent meals and alkalies. Since then she has felt better, although her pains have not been entirely removed.

While, in general, I am opposed to operative treatment in cases of floating kidney, I believe that in rare instances nephrorrhaphy may be justifiable, especially when a connection between the symptoms (both the direct as well as the gastro-intestinal disturbances) and a movable kidney appears to be proven in a high degree, and the above-described dietetic-mechanical methods of treatment have completely failed. At any rate, every surgeon, before advising operative intervention in movable kidney, should completely exhaust the suggestions and remedies of the physician. By proceeding in this manner the vast majority of patients suffering from floating kidney will be relieved of their disturbances without any surgical intervention.

VENEREAL DISEASES—THEIR RELATION TO THE PUBLIC HEALTH, TO SOCIETY, AND TO THE PHYSICIAN.[1]

BY J. W. HAUXHURST, M.D.,
WEST BAY CITY, MICH.

MR. PRESIDENT AND MEMBERS OF THE SOCIETY: My paper is not a scientific discourse in the use of medical technicalities, for I have purposely adhered where I could to plain English to express my thoughts. I fear some of you may think my effort better suited to the pulpit or a missionary meeting than for this occasion.

But if you agree with me that the necessity exists for giving the subject some thought in the manner I here consider it, then I am sure the discussion to follow will interest us and be a benefit to all here. I wish to ratify the authority given to health boards and other proper officials to demand from physicians reports of contagious diseases which they discover in practice. The wisdom of providing such a law and the justice of enforcing it to prevent unnecessary spreading of such diseases cannot but be manifest to any one having reason; and the physician is in this instance the keystone of the arch upon which rest the physical integrity and well-being of the people.

He is here wiser than the State, and he is master of the law; for the one must come to him for instruction and the other can execute only when his decision is made. Upon him therefore is placed the responsibility of preserving the health of a larger patronage than he realizes. How well and truly he performs his task and how well the people heed his admonitions I purpose to show.

The law relative to health matters is conspicuously inconsistent in its failure to attack contagious diseases in their greatest stronghold, and our law makers have never yet had their attention soberly and earnestly called to this inconsistency by physicians. Nor have the people been intelligently educated and aroused to harness themselves with physicians for the purpose of unitedly and perseveringly petitioning legislators to remove this inconsistency.

Syphilis and gonorrhœa are contagious, infectious, and communicable. They are dangerous to the public health and a menace to human happiness. They infect to a greater or less extent a considerable percentage of the people of all nations and tribes on the globe. They prevail and parade in the same garb and swarm with the same detestable qualities, if not with equal frequency, in Christian lands as they do among savages and heathens. They manifest no discrimination in their choice of habitation. The royal and the vulgar, the banker and the baker, the fat and the lean of either sex all alike fall heir to entertaining them as a retributive punishment for indulgence in unclean dissipation. They entail upon the old in their declining days, when life should be a guiltless and peaceful preparation for eternal rest, their plague-stricken footprints and horrifying sores.

Syphilis is a transmissible disease, and it therefore carries with it a sting and a taint for the innocent and blameless babe yet unborn: the sin of a parent's wilful transgression thus becomes the unwelcome heritage of those who deserve a better birthright than a grossly imperfect physical existence, the cause for which they themselves may never know, and the responsibility of guessing the unfortunate riddle for them may bewilder the surmises of many physicians.

Like consumption, diphtheria, and measles, syphilis and gonorrhœa are stamped with their own characteristic marks, and they are distinguished with as unerring certainty as is any disease: each is disseminated

[1] Read before the Bay County Medical Society, March 14, 1898.

only by its individual and specific germ, and neither can in any known way be made to generate or perpetuate the germ of any other disease; so when it is discovered each can be known and called by its proper name.

As to the common occurrence of the venereal diseases, their baneful effects upon the human family, and the percentage of deaths that can justly be accredited to their immediate or remote existence, as compared on parallel terms with other contagious diseases, the experience of physicians in different localities will of course be wide apart.

My own experience has been only that of a general practitioner, covering twenty-two years of urban and rural practice, and with no special effort to get venereal cases. This influences me to conclude that syphilis and gonorrhœa in acute or chronic form, linked with the various grave pathological conditions they create, lead to more misery for mankind than the six other communicable diseases named on the postal cards that have been given me by direction of the Michigan board of health, to be reported for the people's protection against contagious diseases.

According to the weekly statement of contagious diseases reported to the department of health, borough of Manhattan, New York, as given in the MEDICAL RECORD, there have been eleven diseases noticed in these reports since January 1, 1898. They are consumption, typhoid fever, scarlet fever, measles, diphtheria, croup, chicken-pox, cerebro-spinal meningitis, whooping cough, mumps, and erysipelas.

I have taken the statistics here reported because they are fairly representative of those from any large city, because they are current and undoubtedly reliable, and because I believe the comparison made with reference to the Michigan board of health will justly apply to these reports; that is to say, syphilis and gonorrhœa are more prevalent, and are the cause of more suffering to the population of the borough of Manhattan than are all the contagious diseases for which reports are required by its department of health.

The total number of cases of all contagious diseases reported to this health department from January 1st to March 5th is 9,362, and the total of deaths 1,557, or a mortality of about 16⅔ per cent. I think that if any one of the reputable physicians of New York City, who has been in active general practice there for twenty years, will calmly review his business for that time, reflectively analyze his venereal cases, and place to the credit of syphilis its primary pustule in one, its mucous ulcerations of the mouth in another, the gummy tumors of all who had them, the ugly bone lesions of many, the wholesale destruction of the visceral organs in not a few, the dozens of miscarriages due to its effects, and then let him place in the same column gonorrhœa, and credit it also with every male and female coming to him with it, with every stricture he has seen from the disease, with every old man he has seen dying with cystitis as a result of such stricture, with all the pus tubes and ovaries removed by surgeons and directly attributable to it; and again, he can go farther yet, and contemplate how many homes have been disrupted, and how many dishonored wives and mothers and disgraced children have felt the sting of the venereal diseases, and then he will be able to answer and say whether it be the reported or the unreported contagious diseases that prey most heavily upon the health and happiness of the people; and whether in the face of conditions thus stated, it is not senseless parley to discuss these conditions unless they are stripped of all morbid sentiment, or to consider them at all for the public welfare except on the plan of unveiling them without distinction, so that the people can properly recognize them in the same sense that they do all other diseases.

If Mary Jones calls at the dispensary of a hospital with a sore throat, and upon examination she is found to have diphtheria, she will be told so, and the physician will wisely report the fact to the proper authorities for caring for her. They will go to her and inform her that she is dangerous to the public health, and that she will not be permitted to communicate with other persons who are free from her disease. She will be duly quarantined, the entrance to her apartment will be suitably placarded, and the public will thereby have warning to keep away from her.

But when John Jones, her father, calls at the dispensary, and he is found upon examination to have ugly sores upon his penis, the physician smiles in a questioning way, and informs him that he has syphilis; that it is a dangerous disease to himself if not promptly dealt with, and that he will communicate it for weeks to any woman with whom he may have sexual intercourse.

At the same time that John is receiving these instructions his son James is presenting himself at another dispensary for examination and treatment. He also receives an interrogating smile, and is told that he has gonorrhœa; is likewise informed that he will communicate it to any woman with whom he may have sexual intercourse, and for weeks or months at that. Father and son both receive their prescriptions, depart with sordid mien, and without restraint from dispensary authorities, unnoticed by the law, unclean to the public, masked to society, to roam at their pleasure, to contaminate without stint. What parent having a daughter to be reared in this life, and educated under the prevailing rules of society to marriage and motherhood, who would not wish to unmask and forestall a deceitful and diseased lover before she should be united in sacred bondage to him upon whose person she would too late discover concealed the cause for her matrimonial unhappiness, the poison for her own physical ruin, the canker to infest and gnaw the lives of her children, and her grandchildren may be to the third generation?

This picture is not one of imagination, but has its original in more than one instance within my memory and experience, and its importance here to illustrate what is passing unheeded about us every day is not light, because I am sure the majority of physicians can call up in their memories like occurrences. And the application of the picture indicates the need of a remedy to restrict or prevent such occurrences, if possible. Later on I offer a means to help in that direction, and if it appears severe it is because I believe that nothing milder will accomplish what is desired—a decided decrease in the spreading of venereal diseases.

It is my opinion that the majority of reputable men in the profession find it neither agreeable, satisfactory, nor profitable to inspect and treat them. My own experience and my talk with other physicians in this respect lead me to think so. A man who will patiently submit to lying upon his back for weeks under treatment for a fever, or from some injury, and who will accept your explanations on the tedious nature of his complaint with confidence and commendable resignation, and who will pay you cheerfully for your services when he is again well, will walk into your office with the gonorrhœa, look leeringly at you as he takes his seat, and, humiliated by his disgrace, he will begin by adding a lie to his shame and unload the responsibility for his woe upon a strain he received some weeks before. After this silly introduction of his case he will appealingly beseech you to heal him in two or three days, and if you assume the management of his case he will be one of a majority soon to get intolerant of your service, go to some other physician, or be led to try the snapshot of a companion;

and when he is finally convinced that he is cured, his last drug receives the credit. You are remembered by him only in hatred, and have his condemnation without your pay for your pains. A man with a mouth reeking with syphilitic ulcers, expecting to get a start in his treatment for the dollar in his pocket and the balance on his next pay day, will never turn out to be a Klondike to the doctor who takes him on his hands. Women who come into your office with venereal diseases are more brazen than the men, more disgusting to treat, and are less remunerative to the doctor. Physicians bear altogether too much responsibility in their relations with these diseases, and receive too meagre pay for treating them to desire them to continue, notwithstanding the liberal fees announced in society schedules. Therefore doctors can well afford to make alliance with whatever plan is best suited to restrict or prevent them.

The adoption of the scheme for the State to license prostitution by causing all women engaged in it to be registered and regularly examined, would not be the unkindest cut of all to these women, provided every man who goes in to lie with them is first and at each visit himself examined and given a clean bill; and provided further that these women receive from the State a guarantee with their license that if they should become infected in these houses they would receive indemnity. Under such a state of things many married women, I know, would find greater security for their persons here than at home with their husbands, under existing conditions. But as a measure to restrict or prevent the spread of venereal disease the execution of such a plan can result only in apprehending a small fraction of the persons who do the greatest mischief to society in this direction. The keepers of houses of prostitution are themselves interested in having only women who are clean in respect to disease, for the success of their enterprise depends much upon the fewest number possible of their patrons becoming infected on their premises. They entertain complaints from such infected patrons, and cause investigations to be made by physicians among their inmates, for the purpose of finding the source of the contamination; and the woman found with it is either retired or discharged until cured. Men who visit these houses are also moved by surmise to be on their guard, and they take precaution against infection by washing themselves immediately after copulating, a procedure probably not worthless as a protection to them in many instances.

Having in mind that I should some day write a paper of this character, and wishing to be in a position to defend the radical proposition it promulgates, as against the less sensational plan of licensing vice to curtail crime and disease, I have for years made it a practice to question nearly all who came to me for treatment with these affections as to the source of their disorder, and I am convinced from such questioning and the answers received that eight out of every ten persons with venereal disease have contracted it outside of recognized houses of prostitution. This is conspicuously true of gonorrhœa. Many of the women thus specified may be prostitutes in every sense of the term, and they may regularly or irregularly inhabit such houses; but in their excursions outside they stamp the seal of iniquity with terrifying effect upon many an unfledged lad and improvident man. Then there is in every city a class of dissolute young fellows who hunt up companions among young girls who have been reared under lax home government, and as a result of these inauspicious social alliances, carried on at unreasonable hours of the night, undue liberties pave the way for boldness, and the real virtue in many of these unguarded and misguided young girls crumbles gradually away, and one by one they become victims to the curse of which I write. And in this condition many of them, while yet employed as domestics, clerks, or what not, growing more fearless as they proceed with their male associates, are not to be overlooked as a very fruitful factor in perpetuating the disease. There are other places from which trespassers on morality drink every now and then polluted draughts, found in varying numbers in all municipal communities. These are the homes of women of mature age, many of them married but not mated in fidelity, who are not entirely abandoned to vice; yet in their quiet way they maintain lascivious relations with male visitors, and not infrequently one such woman becomes responsible for the sudden appearance in the community where she lives of a half-dozen or more new cases of gonorrhœa or syphilis, and the husbands of noble women and faithful wives are too commonly the victims. The following bit of history from my own experience shows what shocking occurrences will sometimes be revealed to a physician, and points out most emphatically the need of the State's aid to avoid the repetition of like occurrences:

A girl of twelve years, whose father and mother are respectable but heedlessly indulgent with their children, was brought to my office with a vaginal discharge. The case read gonorrhœa in every particular. Several days from the time I first saw this girl a fine little boy of six years came with his mother to my office, to be inspected for a discharge from his penis. A Christian woman, devoted to her children to the verge of self-sacrifice, the mother was at first disposed to regard my statement that her boy had gonorrhœa as an insult to her. It was true, and the disease was obstinate to treat. The boy's home is only a block from where the girl I was treating lives, so I sought to relate them by tracing association between the two. I could not, nor could the mother with all her cunning. Within a day or two from this second discovery I attended a woman in labor, living two blocks from the boy. I was informed on this occasion that her little girl of ten years complained of a discharge which made her sore. Here was gonorrhœa again, and under circumstances which aroused me to a determination to find how it came in this neighborhood, and why it should be with such young persons. I conferred with the little boy's mother, and she had no trouble to get his simple story of the immodest behavior of this second girl with him. I returned to the first girl on a new tack for the history of her infection, and traced it to a girl of eighteen years, whose reputation for depravity went unchallenged and whose diseased condition at the time was a theme for raillery with her companions. She lived but a block from these two young girls, and, as if to attain the culmination of her wickedness or to grasp an opportunity to avenge the loss of her own chastity, she enticed them together to her room and there taught them in their youthful innocence their first lesson in immorality; and with her instructions she communicated to them a disease of more consequence to be rid of than mumps or whooping-cough, one having qualities which render it more dangerous to the public health and society than chicken-pox or measles, one which every respectable physician thinks of with disgust, and examines with greater dread than he does either typhoid fever or consumption.

What I have here pointed out to you does not show all avenues open to the mischief done by venereal diseases, but I have attempted to put enough on record to warrant me to urge that as a menace to immoral and unrighteously inclined parents in times of temptation; as a warning to young men and young girls against indifference to the principles of chastity, and as a reminder to them that the people have expressed a respectable regard for the purity and safety of girls and women; as a check upon the lewd, depraved mem-

bers of society, whose persons are never free from pestilence, who relish indecent and lustful associates, and who love to boast of their seduced victims as though a reward of merit had been offered for the extermination of virtue—for these reasons, and as an offer to improve the social and physical welfare of all mankind impartially, disregarding all sentimentality, heeding no exceptions in its expression of the law, the State should print syphilis and gonorrhœa upon its public-health postal cards, along with other contagious, infectious, and communicable diseases. Of course I realize that this is a most radical proposition, and I presume many of you will at first be inclined to receive it as a jest. It is not made without first contemplating seriously the embarrassments which such a step would place upon the complex structure of society as it at present exists, and what a rebuff it would receive from all who are disposed to regard venereal diseases as merely unfortunate accidents happening along the trail of the amorous relations between the sexes; who look upon such relations as practically indispensable, and upon such accidents as being surrounded by circumstances which render them pre-eminently privileged. I fully comprehend the impulsive character of the sexual passion, and recognize it as a natural physiological function necessary to the end of perpetuating our species. I argue only in favor of its curtailment within its lawful limits, and of its restraint when it is diseased and dangerous to others. You will say that if the State should ask it of them, neither physicians nor others possessing the knowledge would report to officials the names of persons having these diseases. I grant that at the beginning of such an innovation only rarely, compared with the number of cases occurring, would reports be made; but they would be of the class most prolific in the reckless distribution of the germs. They would be the impudent and dissolute chaps who boast with disgusting pride among their fellows that they have the pox, and regard their repeated doses of the gonorrhœa as of little moment to themselves or others, as if they had acquired a fresh cold; and who delight in "springing" jokes on their chums by directing them to the source whence they became infected, perfectly indifferent to the far-reaching and disastrous results to come from it. They would be women hardened to iniquity and disease to the extent that they harbor both as harmless possessions, to be cultivated and shared with others at every opportunity. There are physicians who would comply with the law and report many such cases. Circumstances would lead many of these victims to report others of their companions, and enough of them would go on record to deter many others from continuing libertine lives.

When John Jones has been reported to the health department as having syphilis, and James Jones has been reported as having gonorrhœa, what will be done with them? Have the proper official go to each of them with a notice, in printed form, containing the section of the law relative to contagious diseases, inform him that if he communicates his particular disease to any other person he will be punished according to the terms of the specific law.

Even if every physician should find the majority of the cases he discovers to be surrounded by circumstances amply justifying him to keep them secret, and only now and then at the beginning a report comes from another source, yet the method I propose for the restriction and prevention of venereal diseases will gradually wedge itself with favor into public opinion, and with less and less friction as its beneficent results are realized by the people.

Even criminal law has at times been diverted from its proposed lines of action by some extenuating circumstances connected with the deeds of culprits, whereby guilty ones have escaped justice; but the need of a law against criminal acts is none the less a just and desired measure because of that fact, and no one can doubt the restraint it places upon the conduct of many who by inclination would commit crime without its warning presence.

With syphilis and gonorrhœa printed upon the public-health postal cards, side by side with other contagious diseases, and all subject without distinction to the same sanitary law, not only would it deter thousands through fear of public exposure from risking their persons to the chances of infection that they now so recklessly incur, but the general public would have liberal opportunity to become enlightened from a reliable source and in a convincing manner by the literature, charts, and statistics which would be distributed by health boards concerning the alarming frequency of and danger from these diseases; and respectable people at least would soon be taught to view them with the serious consideration they deserve.

All participants at the communion table would have revealed to them the real significance of having individual cups for this holy service, and the actions of judges at our courts in deciding to exempt affirmers from kissing the Book, because they reasonably think that disease has been by this practice communicated from one person to another, would be correctly interpreted and rightfully upheld by those conservative people who now oppose these two innovations, and regard them as a meddlesome step toward extreme nicety and an unjust departure from a proper solemnity for these occasions. For the introduction of these praiseworthy changes the active and intelligent physicians can claim credit, and it will be by their influence, backed up by their experience in practice and armed with reports of genuine instances to prove what they preach to elders, ministers, and judges, that the new order will continue to prevail and expand.

It is the mouth sores of syphilis which physicians have chiefly in mind when they advise this caution, and the people should be plainly told so through the agencies I have mentioned.

If Dr. William Osler could speak specifically to the people, and to their full comprehension, as he does in the concrete to physicians when he says to them, "Know syphilis in all of its manifestations and relations, and what remains to be learned will not stretch the pia mater of a megalocephalic senior student," they would be surprisingly impressed with the paradoxical revelation that the health departments had been hoodwinking them with bluster about attacking contagious diseases, the most frequent of which and the ones presenting the most terrible danger to the public having been overlooked and ignored by them altogether.

It requires only a moment's reflection to conceive what a calamity it would be to mankind if to-day persons with leprosy were allowed to mask their spots and mingle promiscuously with the people, or if patients with diphtheria and small-pox were permitted to go about unnoticed and unrestrained; and we all know how limited are these diseases, compared with the population, as the result of the State's efforts to restrict and prevent their spread under present sanitary methods.

Venereal diseases on the other hand are increasing appallingly all over the world, and yet it requires only that the State should apply the same sanitary methods to them to have their presence correspondingly diminished. I have faith that the State will some day rise to the loftiness of its duty, and under not only national bnt international regulations all contagious diseases whatsoever will be lawfully noticed and satisfactorily controlled.

YELLOW FEVER OF THE TROPICS.

By WOLFRED NELSON, C.M., M.D., F.R.G.S.,
NEW YORK.

THE following is supplemental to my article on yellow fever that appeared in the MEDICAL RECORD of last week.

The sequelæ of yellow fever are numerous—among others, pimples, boils, swelling of the parotid glands, at times suppuration, etc.

Malaria.—The rôle of malaria in the tropics is a constant quantity. No one living in the tropics escapes. Dr. Girerd, at Panama, devoted a great deal of time to examining the blood of Frenchmen who came to Panama while work was in progress on the Panama Canal. The blood of new comers from France was normal. After a month's residence he examined it again; malaria had made its impress in every instance.

So much by way of preface. I recall cases of yellow fever occurring in men who had been on the isthmus of Panama some months ere contracting yellow fever. After convalescence began, well-marked malarial manifestations were in order. The intercurrent rôle of malaria in tropical disease is so well known that any comment may be omitted.

Another condition met with in such convalescents, especially in the severe cases, was the very slow pulse. Its slowness, while the disease was active, has been dwelt upon. Its slowness during convalescence will cause much surprise to those to whom the disease is a new one. At times it will be found as low as 35 and 40. It remains slow—at times for days together. Gradually it gets back to a normal standard, as strength is regained.

The temperature in many cases during the early days of convalescence will be subnormal—97.5° - 98° F. In many cases this will be observable for days. In the cases in which malaria is an element, after days it will run up and show its own characteristics, when small doses of quinine are in order.

When death follows, the body is that of a well-nourished individual. The majority of its victims are men and women previously in full health. Death has come so quickly that the wasting has been almost *nil*.

The rich tinting of the skin in the convalescents may remain weeks and occasionally months.

The sending of the convalescents to a northern climate to complete convalescence is very necessary. Convalescence is much more rapid. When fully restored they can return, forever immune.

I have yet to learn of a case of secondary yellow fever in any one who has had specific yellow fever. I have compared notes with many profoundly versed students of yellow fever. I fail to recall a single exception to this statement, and it embraces my own as well as the experience of practitioners in the several localities named.

Post-Mortem Findings.—My post-mortem work simply confirmed what an old-time and clear-headed American writer on the disease has stated: "Yellow fever has no pathology." Dr. Grenville Dowell's brochure is an "arsenal of facts."

The conditions found are so variable, in patients cut off by the disease and who have had the same symptoms, that no fixed reliance can be placed upon them. Kindly recall my earlier statement, embodying my view, that it is a blood disease and that the poiso expends itself in the blood. If this view is accepted, any marked pathological changes, except in the blood, need not be expected—save those in certain organs due to imperfect nutrition caused by the impaired blood.

The Liver.—Many writers on yellow fever dwell on the liver. That so large and so important an organ should suffer will not surprise one familiar with malaria and tropical disease.

The yellow or chamois-skin liver is supposed to be the characteristic liver in yellow-fever post mortems—that is, according to the text-books. I never saw but one, and that was the result of upward of one hundred post-mortems conducted by Dr. Didier, an M.D. of Paris, and the physician-in-chief to the Panama Canal hospitals at Panama.

In my own post-mortem work, I have found it presenting a normal appearance to the eyes; again, fatty, with an easily detached capsule; yet again, fatty and on section showing many tiny oil globules. In the latter case the patient, a Scotchman and a physician, a large heavy man, had been stricken with the disease a few days after landing at Panama. In short, nothing constant in this organ.

The Kidneys.—Again no constant condition. Many normal to the eye; others large, in harmony with the hepatic degeneration. In several cases the kidneys appeared to be smaller than normal.

The Stomach.—In view of the great pain and constant vomiting, including "black vomit," one naturally would expect to find in it marked pathological changes. It always presented signs of marked inflammation. Coats thickened. It contained more or less black vomit. In one case I found all of a pint of it. Frequently the inner surface showed many foci or well-marked minute points of a deep carmine hue. Again, small spots of blood, adherent to the wall of the stomach.

Dr. Castellanos, then a physician at Panama and physician to the Military Hospital, had had a very large hospital experience in his native island, Cuba. He told me that it was the only constant condition found by him in yellow fever, *i.e.*, signs of acute inflammation of the stomach. While in Cuba he had made nearly one hundred and fifty autopsies in yellow-fever cases.

Drs. Didier and Castellanos jointly had made nearly two hundred and fifty autopsies. A number of us at Panama were working in close touch and in perfect harmony, constantly comparing notes.

Dr. Castellanos' early field had been Cuba, where a history of the disease has been recorded for over one hundred successive years.

Dr. S. Didier, a native of Martinique, French West Indies, came from a centre frequently swept by epidemics of yellow fever.

Dr. Girerd, my brother, the late Dr. George W. Nelson, and myself—we had to face it in epidemic form, as strangers, and learn of its death-dealing powers.

The Brain.—Dr. Didier, in his large experience, found "*rien digne de remarque*"—"nothing worthy of recording."

The Intestines.—Frequently they contained the "black-vomit stools"—a dark, pitchy substance, or altered blood. The motions of such patients by many inexperienced men are deemed a diarrhœa.

The Bladder.—Generally it contained a few drachms of highly albuminous urine. Remember the previous suppression.

Among other noticeable things, the body retains its temperature for many hours after death. Its coloring was very pretty—a light canary-yellow, with spots in dependent situations of a mulberry tint on a yellow field. Its early and great rigidity was very marked.

Regarding black vomit, nearly all the cases in which it appears end fatally. The French writers on yellow fever happily name it *marc de café*, or "coffee-ground vomit." The name is clear and very expressive. It has a peculiar odor, an odor very difficult to describe. Confusion may arise in the minds of students of yellow fever when the disease is new to them. Are the vomited matters bilious in character or do they contain altered blood? Of course I know what the mi-

croscope tells us of such material. To clear up the question of bile, I collected some black vomit from a Swede, a sailor, whom I had under observation in hospital, and tasted it. It was faintly acid. As I had had the disease at Panama during the epidemic of 1880 I did not deem the experiment as being in any way dangerous to me. I wanted to dissipate a doubt, and that was the only way to do it.

Black vomit is an indication of blood changes. Blood exudes from the mucous surfaces. In women quantities of blood come from the vagina. Frequently the tongue in fatal cases becomes a fiery red; as it loses its mucous membrane the blood exudes—a very bad symptom.

When black vomit is allowed to settle, the altered blood goes to the bottom of the vessel, while the upper fluid resembles in color weak black tea.

Regarding the blood found post mortem, I always found it in a fluid condition. Two hours after death I got enough to take its specific gravity. It was normal.

As I have stated in my earlier article, Dr. Girerd examined the blood microscopically in a fatal case, and failed to find a single red corpuscle. Let us remember the very large amount of albumin found in the urine—often twenty-five and fifty per cent.

To repeat, I deem yellow fever of the tropics a blood disease pure and simple. I have held this view since 1884. If I am right in the matter, we have, I think, a full explanation of many of the symptoms of yellow fever and the absence of many looked-for pathological changes. The symptoms and changes are due to necræmia or death of the blood.

Virchow attributes loss of consciousness to the failure of the red corpuscles to carry oxygen.

Much remains to be explained about yellow fever. It is our old enemy. Many honest and patient toilers are at work on this great and timely problem.

Dr. Domingos Freire, of Rio de Janeiro, Brazil, was the first investigator along a special line. In 1879 and 1880 he commenced a series of experiments with earth taken from over the bodies of yellow-fever victims buried in the Sta. Isabel Cemetery, near the city of Rio de Janeiro. The earth was washed. With the washings he made cultures, and later injected the fluid into the tissues of guinea-pigs. Result, fever, great disturbance, and death. Next he took blood from yellow-fever patients and made cultures. The early or strong cultures killed the animals used for experimenting. Later, attenuated cultures were used, when the animals showed some febrile movement and escaped. Next, he used on the animals so protected the strong cultures, and they all escaped. In the animals not made immune the strong culture killed them without exception.

Next, he dealt with man. Years of time, study, and research have been devoted by him to an effort to solve this great question. He believes, and many familiar with his work, including the writer, believe that he has found a fluid or culture that, injected into the human body, causes a mild type of yellow fever and that it confers a certain immunity.

Vaccine is used to protect us against small-pox. Much of our reasoning regarding vaccine and its exact rôle in the human body is empirical. It protects, and that seems to be ample for general purposes.

The fact remains that Dr. Domingos Freire has been indorsed by the government of Brazil; that a considerable sum annually has been voted to aid him in his excellent work — work faithfully carried on along Jennerian lines.

I have been familiar with Dr. Freire's work from its inception. If my memory is right, I was the first to translate his early reports—back in the early eighties.[1]

[1] Canada Medical Record, Montreal, 1882–83.

Dr. Carlos Finlay, of Havana, for many years past has been experimenting along the same lines, making cultures, etc. In 1887, I had the pleasure of comparing notes with him in Havana and of examining his cultures. Dr. Delgado, of that city, was associated with him in the work.

Dr. Freire named the germ discovered by him the cryptococcus zanthogenicus. Dr. Finlay named the germ found by him the cryptococcus tetragenus flava.

Dr. Finlay, fully twenty years ago, pointed out the mischief caused by mosquitoes in transmitting disease, particularly yellow fever. This function of the mosquito seems to have been rediscovered of late.

Dr. Girerd, at Panama, following along the lines laid down by the discoverer, Dr. Freire, made cultures from the blood of yellow-fever patients. When they were sufficiently attenuated, he gave himself a few injections, but did not push it to full immunity. Then he proceeded to give the best possible proof of his faith in the matter by a crucial experiment in his own person. In the yellow-fever building of the Panama Canal Company (acting on Dr. Finlay's discovery) he allowed mosquitoes to settle on a man who had severe yellow fever—man in fifth day of the disease. Later the mosquitoes were captured and allowed to settle on Dr. Girerd's hands. At the end of two days he had the symptoms described by me under the heading mild yellow fever. His case was watched carefully. All the symptoms were noted. Albumin was found in the urine. His personal experience I duly translated and it was published in the *Canada Medical Record*, Montreal, in 1885, together with an editorial.

The honor and credit in this matter are due wholly to Dr. Domingos Freire. His work was confirmed by Dr. Finlay, in Havana, and by Dr. Girerd, at Panama. The gentlemen named have worked in perfect harmony, seeking a common end—the good of their fellow-men.

Dr. Domingos Freire's latest work on this matter has just been issued, and its title is as follows: "Mémoire sur la Bactériologie, Pathogénie, Traitement et Prophylaxie de la Fièvre Jaune." The above memoir of one hundred and sixty-one pages was duly presented to the Madrid International Congress of Hygiene and Demography, that met there in the spring of this year.

The Bacilli of Beriberi.—Dr. G. Nepveu describes three varieties of bacilli which he has isolated in the blood of beriberi subjects: the large, the medium-sized, and the small bacillus, as he terms them. The large bacillus is seldom found in the blood-vessels, and then only in association with the two other forms; it is demonstrable in the kidney, in the glomeruli, in the convoluted tubules, in the loop of Henle, and occasionally in the tubuli recti. It is 6–10 μ long, and 0.3–0.4 μ wide; is straight or slightly curved, with rounded, dark-colored ends, and has a distinct capsule. The medium-sized bacillus is 3–4 μ long and about 0.3 μ broad. Like the former, this bacillus shows also, after proper staining, alternate light and dark areas. It is found in abundance in the arteries, capillaries, and veins of the kidney; sometimes in almost pure cultures. The small bacillus exists in large numbers in the blood; it is as long and about one-half as broad as the tubercle bacillus, and is bent at a slight angle. It is found close to the border of the red blood corpuscle, giving it a toothed appearance. The writer thinks it possible that these three forms are identical. The large and medium-sized varieties show a marked resemblance to the bacillus of chicken cholera and of rabbit septicæmia.—*Centralblatt für innere Medicin*, No. 11, 1898.

THE ROENTGEN RAYS IN SPINA BIFIDA.[1]

By CARL BECK, M.D.,

PROFESSOR OF SURGERY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; SURGEON TO ST. MARK'S HOSPITAL, ETC.

In speaking of spina bifida one is apt to think only of its cystic form and of its location in the lumbo-sacral region. But besides this most common type there are several others, which require to be distinguished before we can choose the proper therapy. Thus it cannot be a matter for indifference whether there is (1) a so-called simple meningocele—in other words, a hernia-like protrusion of the pia, containing cerebral fluid; or (2) a myelomeningocele, a frequent variety, which is characterized by the spinal cord expanding itself, like the optic nerve in forming the retina, around the protrusion, and, together with the pia, constituting the sac; or (3) whether there is a myelocystocele—that is, a tumor caused by cystic dilatation of the central canal of the spine.

It is also important to discriminate whether the tumor is situated in the cervical, dorsal, lumbar, or sacral region. If situated in the cervical or dorsal region, the cord cannot protrude into the hernial sac, as it does in the lumbar or sacral portion, which corresponds to the end of the cord. It is also desirable to know whether there is a hiatus in the spinal column, and how extensive it may be; and furthermore, whether or not the fluid contained by the tumor can be dislodged into the spinal canal.

In view of these anatomical distinctions, it will be easily understood that simple meningocele gives the best chances of a cure. Whether injection treatment or extirpation, however, should be preferred, is not yet agreed upon among the profession. I have cured three or four cases of simple meningocele by repeated aspiration, followed by the injection of a few grams of a ten-per-cent. iodoform-glycerin emulsion; and I generally prefer injecting to extirpating, provided the surface of the skin be normal. But if there be well-developed gangrene, or even any considerable abrasion of the epidermis, then septic infection of the cyst wall cannot be arrested unless immediate and extensive removal is undertaken.

On the other hand, myelomeningocele and myelocystocele offer a less favorable prospect. In these cases the injection treatment is always a failure. If in myelomeningocele the nerves are freely dispersed in the sac, the area medullaris vasculosa, after being circumcised, must be reduced into the vertebral canal, and the union of the soft tissues above must be perfected in the most minute manner. If the nerves have dishevelled themselves in the wall of the sac, the latter, after having been freely exposed, must be reduced in the same way. If situated in the lumbo-sacral region, the preservation of the nerve strings is of but little importance.

In myelocystocele the reposition should be made in the same manner. If there be any opening in the bone, protection should be sought by covering it with strong flaps, consisting of integument and muscle. It goes without saying that such delicate operations must be performed only after the most rigid aseptic precautions. Hemorrhage can be reduced to a minimum by temporary constriction, applied by a small rubber tube and by methodical interrupted compression.

According to the unanimous opinion of all authors known to me, one of the greatest difficulties encountered in the treatment of spina bifida is that its various types cannot, as a rule, be defined before operation; between meningocele and myelocystocele, indeed, the certain distinction is (often) quite impossible. Sometimes conclusions may be drawn if an opening of the bone can be palpated, or if a portion of the fluid can be reduced into the spinal canal by pressure. Paralysis of the lower extremities, of the rectum and bladder, all point to the existence of myelomeningocele; but all these signs are far from being absolutely reliable. Considering only this one point—that in meningocele aspiration should be tried first, while in the other varieties extirpation should be resorted to—it must be admitted that our deficiency in scientific knowledge makes itself felt rather strongly as regards therapy. Some authors advise opening the lower portion of the tumor first, in order to ascertain whether the spinal column is open, as in myelomeningocele, or not open, as in meningocele. Koenig and Hildebrand go so far as to emphasize the necessity of ascertaining how the nerve strings are dispersed, by first making a lateral incision into the tumor, even after they can state that there is a myelomeningocele.

All these procedures, the reason for which no surgeon would dispute until recently, are now rendered entirely superfluous by the discovery of the Roentgen rays. The skiagram shows with absolute distinctness not only whether there is an opening in the bone, but also tells of the presence and sometimes even of the expansion of the nerve substance in the sac. In those rare cases in which the presence of lipoma or fibromyoma is in question, it is again the skiagram which gives the needed information.

The skiagram which I had made represents a formidable specimen of the lumbo-sacral type of spina bifida, and serves as an illustration of these views. The integrity of the spinal column and the cystic character of the contents of the sac are there apparent. (If any nerve strings were present, a marked shading would be noticeable.) In this case a very extensive gangrene of the surface of the tumor induced me to resort to extirpation, which verified the correctness of the skiagram. Had there been no gangrene, I should surely, on the testimony of the skiagram, have selected the injection treatment.

The patient, a boy, was five days old when the operation was performed. While this article goes to print, four weeks after the operation, he is doing well.

[1] Case presented at a meeting of the physicians of the German Poliklinik, March, 1898.

Progress of Medical Science.

The Therapy of Carcinoma of the Rectum.—Dr. Hochenegg has operated in 129 cases of rectal carcinoma since 1890; of these 34 were colostomies, 89 sacral extirpations, and 6 perineal amputations (*Wiener klinische Wochenschrift*, 1897, No. 32). Of the 89 sacrally operated cases, 8 were fatal, though 3 of the deaths had no connection with the operation. This is certainly a magnificent record. The writer refuses operation in cases of marked general debility and when there are symptoms of internal metastases; in cases in which the tumor is immovably fixed in the pelvis; and when the glandular infection cannot be limited by the examining finger. Adhesions to the prostate, bladder, vagina, or uterus form no contraindication to a radical operation, since these organs can if necessary be extirpated. In doubtful cases a colostomy is at first performed; two weeks later, when the tumor becomes less fixed, the extirpation is done. Symptoms of acute intestinal obstruction also form a contraindication to radical operation. Radical extirpation may be performed by either of two methods, different in principle: perineal and sacral. Hochenegg applies the perineal method in those cases also in which the carcinoma has not involved the anal portion very high up and in which the rectal mucous membrane is soft and easily movable over the tumor. In all other cases he prefers the sacral operation.

His procedure in the sacral operation is as follows: With the patient on the left side, a convex incision is made—with the convexity toward the right—from the left sacro-iliac synchondrosis to the right lateral border of the coccyx. After the skin has been raised, the coccyx is extirpated and the left wing of the sacrum is chiselled off; in extensive carcinomatous disease the sacrum is severed transversely. Further procedure depends upon the location and extent of the tumor. If the anal portion be also involved, an incision must be made around this portion; the rectum is then isolated and amputated to a point above the site of the neoplasm; the lumen of the remaining rectum is drawn down and sewed in the place of the removed anus, or is brought under the skin at the site of the removed sacrum (anus præternaturalis sacralis); the writer prefers the latter method. If the anal portion be not diseased and the sphincter intact, the severed rectum and the healthy anus are sewed together; this is the "ideal" operation. To prevent separation of the line of suture, because of the insufficiency of the circular stitch, Hochenegg proceeds as follows: The tumor is isolated and cut off above, and is then isolated below, but not yet amputated. The healthy rectum above is then isolated and the amount of its mobility is tested. If this portion of the rectum can be easily brought to the anal opening, the tumor is cut off transversely at a point one centimetre above the sphincter, the anal portion everted and freed of its mucous membrane with forceps and scissors; through the tubular wound surface thus produced the healthy rectum above is drawn and is sutured *in situ*. There are two rows of sutures: one, introduced from the outside, in front of the anus; the other, introduced through the sacral wound. Finally, the ring of the sphincter is connected with the rectum by several buried sutures. If the healthy rectum above is not sufficiently movable to be brought so far down, less of the anal portion must be sacrificed. If the rectum cannot even for a short time be brought through the anal opening, nothing is left but to introduce the sutures through the sacral wound. After the introduction of the sutures the writer leaves enough of the wound open to secure drainage. The bowels are moved after the fifth day of operation. At the slightest sign of phlegmonous inflammation, the whole wound is immediately reopened and drained.

Antidotal Action of Pulped Nervous Tissue upon Strychnine.—M. Toniot and M. Georges Brouardel communicated to the meeting of the Hospitals Medical Society held on March 29th, some observations of M. Widal and M. Nobécourt on the antitoxic action of pulped nervous tissue upon morphine and strychnine. If a mixture of one gram of nerve substance and a fatal dose or even twice a fatal dose of sulphate of strychnine is injected into a guinea-pig, M. Toinot and M. Brouardel found that the animals in question invariably lived. The observers made researches into the cause of this interesting fact, and found that strychnine was really present in the mixture, that it had not lost its toxic properties, that dilution of the poison made no difference, and finally that guinea-pigs thus experimented on, if treated with a fatal dose of strychnine, forty-eight hours afterward always died, showing that they were neither refractory nor immune. M. Toinot and M. Brouardel also tried the effect of fatal doses of strychnine mixed with various inert substances, such as charcoal, talc, potato starch, and spinach, and they found that an admixture of these substances had the same preservative effect as nerve pulp, if used in the same proportion and doses. Results were just the same whether the mixture was made twenty-four or forty-eight hours previous to the injection or immediately before. The explanation of these results is in reality very simple and is easily verified by a chemical experiment. Mixtures of carbon, talc, or nerve pulp with strychnine give a filtrate which is absolutely non-poisonous to guinea-pigs, and which when tested shows not the least trace of poison, which, however, can be extracted from the material left behind on the filter. It is obvious, then, that in an injection of this mixture the poison is so fixed and held that it cannot act as a whole, but is set at liberty only very gradually, and the very slowness of this action prevents a mortal dose being set at liberty at one time in the organism. Chemists know well that a solution will give up to inert bodies in certain cases that which it holds in solution, and organic pulps have the same inherent properties and play the same part as inert bodies, as is evident by these experiments. These facts show, moreover, that we must not be too hasty in ascribing antitoxic properties to animal tissues.—*The Lancet.*

On Compensatory Hypertrophy of the Suprarenal Capsules.—Dr. Simmonds, in an article read before the Biologische Abtheilung des Aerztlichen Vereins, Hamburg, March 8, 1898, says that the fact that there are ofttimes no symptoms in extensive disease of the suprarenal capsule makes it probable—reasoning from analogy—that other healthy portions of the capsule become hypertophied and take up the proper function of the gland. He describes such a case, in which one suprarenal capsule was atrophic (weight, two grams), while the other was hypertrophic (weight, fifteen grams). The hypertrophic gland was normal both microscopically and macroscopically; the atrophic gland showed connective tissue and smooth muscle-fibre bundles scattered throughout the gland. In one corner of the atrophic gland were found isolated miliary tubercles, proving these to have been the cause of the atrophy. The speaker described his experiments on animals, in which, after a one-side extirpation of the suprarenal capsule, there was always a vicarious compensatory hypertrophy of the remaining gland in a short time. From these experiments and from his observations on man, Dr. Simmonds concludes that these capsules belong to those "pairing" organs of the body, in which one undergoes vicarious hypertrophy upon disease of the other.

Experiments on the Therapy of Infected Gunshot Wounds.—The experiments were made by Dr. H. F. Koller (*Deutsche Zeitschrift für Chirurgie*, Bd. xlvii., p. 211) with bacteria cultures virulent for rabbits, yet not so virulent as necessarily to cause death. Weak cultures of staphylococcus aureus, pyocyaneus, and a streptococcus capsulatus were employed. The experimental gunshot wounds were all made in the thigh, without doing injury to the arteries, nerves, or bone. The after-treatment of the wounds was conducted in the following series: (1) In the control animals a simple bandage, with or without suture; (2) energetic thermo-cautery; (3) pencilling of the wound with strong tincture-of-iodine solution; (4) drainage of the wound with iodoform gauze; (5) glass drainage; (6) disinfection of the wound with carbolic-acid solution (five per cent.). The interesting and practical results showed that the control animals treated with the simple bandage, and the other animals treated with glass drainage or iodoform-gauze drainage, and one (infected with pyocyaneus) treated with five-per-cent. carbolic-acid solution—were all cured. On the other hand, the remainder of the animals treated with five-per-cent. carbolic-acid solution and those treated by iodine tincture and thermo-cautery all died. This proves that, despite the destruction of germs in the wound, the bacteria infected surrounding tissues and thus did much harm.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 13, 1898.

THE SOLDIER AND THE MEDICAL DEPARTMENT OF THE ARMY.

NOTWITHSTANDING the complaints of the entire press of the country regarding the neglect of the sick and wounded in our late battles, the secretary of war seems to be content to dismiss the whole subject with the statement that whatever occurred was to have been expected and that in reality no one was to blame. In other words, he wishes it to be understood that there was no way to prevent the sending of transport ships loaded with soldiers and without medical supplies or surgeons, the crowding of soldiers into quarters not fit for cattle, and the neglect of the sick and wounded exposed as they were on the battlefield for days together without medical or surgical assistance. It is hardly warrantable for him to say that these are not facts, even if they were based only on newspaper reports. The surgeon-general of the army, in the last issue of the MEDICAL RECORD, in answer to our former queries, makes from his standpoint an excuse for shortcomings in his department, but does not wholly explain why such excuse should have been necessary. The dreadful fact stares every one in the face that the poor soldiers, who had a right to expect everything from a country for which they were willing to sacrifice their lives, really did not receive as good treatment as would have been given to ordinary cattle under like circumstances. Close and filthy quarters, bad food, and foul water were the disgraceful incidents connected with the incoming voyage of one transport after another. These were hardly the ordinary accidents of war, considering the ample time allowed the authorities for preparing for such emergencies.

Every one having responsibility in the premises is ready with some sort of excuse, but none seems to be able or willing to discover the actual guilty parties. The surgeon-general in a measure accounts for the misery and suffering of the sick and wounded by saying that the medical supplies were left behind at Tampa. Whose business was it to have prevented such a gross neglect of ordinary duty? If the general of the army is to blame, he certainly should be called upon to add his quota to the long chapters of explanations from other army officers. Who was the medical officer in charge of these supplies, and why did he not protest at the right time and in the right way as soon as he discovered the true nature of the situation? It was his business to remind his superior officers of the facts, and thus absolve himself from all responsibility in the matter. But apparently he said nothing until called to account by the surgeon-general and then he throws the blame on the commanding officer at Santiago. But General Shafter says the entire responsibility rests upon the medical department.

It seems proper and just, and it ought certainly to be possible, that the blame should be fixed directly on some party who can be proved guilty by a properly conducted and reasonably exhaustive examination into all the facts in the case. Even the secretary of war cannot hush up a proper inquiry because he may for reasons of his own think that it would not be either interesting or instructive. It has not yet been made clear why some of the transports came to New York without medicines, and in one or two cases without surgeons. Surely the commander-in-chief did not leave the surgeons side-tracked at Tampa along with the quinine pills. This sending of sick troops on a sea voyage without surgeons, medical supplies, or even digestible food is too serious a matter to be dismissed with a mere statement that such was not the case and that all the newspapers misrepresented the actual condition of affairs. Those at the front who had the matter in charge should throw some light on the whys and wherefores of such lamentable results. The surgeon-general still owes it to the public, to the profession, and to the noble, faithful, and energetic members of his corps to urge the fullest investigation into all the facts, and to answer still more effectually than he has thus far done the widespread criticism of the management of his particular department. We have some facts, but many more have still to be presented before the real blame can be made to rest where it should properly belong.

THE AMBULATORY TREATMENT OF FRACTURES.

DURING the past few years much has been written concerning the ambulatory treatment of fractures of the long bones. A great deal of interest has been manifested, both here and abroad, and a great deal of confusion, more than is warranted, seems to exist in the minds of some who have spoken and written upon the subject, as to exactly what ambulatory treatment is. Many of those who have discussed the question appear to be under the impression that the ambulatory treatment of fractures consisted in the application of a plaster-of-Paris splint, say to a fractured tibia, in the usual way, and the allowing of the patient to get about on crutches as well as he might be able to do. This method of treatment can certainly not be designated ambulatory, in the sense in which the term should be used. The patient is undoubtedly getting about, but it is largely his determination or his necessity and his success in learning to use crutches that enable him to do so. In these instances the discomfort of the

patient is apt to be much increased by the swelling of his foot, which results in part from its dependent position and in part also from the fact that the muscles are not acting, and consequently are not assisting venous return.

Those writers and speakers who have the clearest conception of what ambulatory treatment really is have given us quite another picture. Still taking a fracture of the tibia with or without a fracture of the fibula as an example, we have described to us a radically different but superficially similar procedure. This true ambulatory treatment consists in applying the plaster of Paris to the limb so that it is suspended in a rigid case from the knee down, and is enveloped in soft material with a thick pad under the foot. The weight of the body in attempts at walking is carried by the splint, which must have a thickly padded collar of plaster of Paris at its upper end, just below the tuberosities of the tibia, upon which the weight of the body rests. The whole splint must be strong enough not to "buckle" under pressure, and still must not be so heavy as to prevent the patient getting about with ease. If we apply such an apparatus soon after the occurrence of the fracture, and allow the patient to attempt to walk, perhaps with the aid of one or two canes at first, we are really employing ambulatory treatment. The success of the method will of course depend to some extent upon the nature of the fracture, and we shall also find that patients will vary very much in their inclination to avail themselves of the possibilities of this method.

Fractures close to the knee-joint, especially if there is any comminution, would be better treated by some other method. Fractures of the femur may in some cases be treated by the ambulatory method, but the apparatus must necessarily be much more cumbersome, and the difficulty in maintaining sufficient extension may be considerable.

There is another side to the question in introducing a therapeutic measure which seems so different from accepted methods. Many surgeons would hesitate, and very justly, to attempt this form of treatment, because of its effect on the mind of the patient. The idea that a broken bone must be "set" and held firmly in position is so well fixed in the minds of the laity that, if we should neglect to go through some process which we must describe as "setting" with subsequent fixation, we may leave a germ in the patient's mind, the mature fruit of which will be a charge of incompetence and neglect, and a suit for malpractice in case the result should not be perfect, something which can practically not be absolutely guaranteed. Wrapped up in this idea of "setting" is the idea that fracture of the leg must be treated by rest in bed, so that the bones may "knit."

It is for such reasons that our treatment of fractures, especially of the long bones, has been of the most conservative nature, and our hesitation has been so great to depart from the old lines. However, in selected cases, this ambulatory method has given results good enough to encourage us to go on with it, and to attempt to define the limits within which it should be applied.

THE HEROES AT THE REAR.

Amid all the bitter charges of culpable inefficiency in the medical, commissary, and quartermaster departments at Santiago, there has never been anything but praise for the noble work of the surgeons in the field or in the fever camp at Siboney. Few in number and handicapped by the lack of almost everything usually regarded as indispensable in operative surgery as well as in the treatment of the sick, these men worked on and on, day and night, in sun and rain, without food and without rest, doing what they could with the little they had at hand for the relief of suffering and the saving of life. A *Sun* correspondent, who visited Siboney after the army had passed on and the fever-infected town had been burned, describes the scene in a few words:

"The train was an hour and a half lurching down to Siboney. What a forlorn, repulsive place it was, all ruins and soiled tents, the air impregnated with sickening hospital odors! The tents covered the wounded and sick who had not been taken off to the cool relief ships and the twenty-fourth (colored) infantry. Sullen and listless, the soldiers sat about their tents as if hating their fate and dreading the fever, and no sound came from the wounded. The hospital doctors were quiet and thoughtful, and their eyes sometimes scanned the sea for a sail, which was force of habit. They seemed to be unsociable, but they were weary almost unto death. These men were the heroes of the rear, and they deserved the medal of honor even more than the men who had led their companies up to the trenches on San Juan. The story of their devotion to duty and sublime unselfishness can never be written, but if there is a recording angel it was not in vain."

Here were no deeds of valor aroused by the din of battle, the fever of action, or the example of others—only the higher heroism of the man who does his duty as he finds it, with no hope of reward other than the ineffable peace of a quiet conscience.

Another correspondent writes of the surgeon in charge at Siboney: "A stocky figure in a faded service uniform of brown, a round, full face with a quiet gray eye, almost a sleepy face, and you have Major La Garde, in charge of the hospital for wounded at Siboney. He always wore a linen helmet night and day. No one ever saw him lay it aside, certainly not during those awful nights in the beginning of July, when the groans and moaning of the wounded were heard ceaselessly from the cots of sufferers. It was La Garde over whose face the tremor of sympathy ran when a badly wounded man was brought in, and when the procession of unfortunates grew it was La Garde who bustled about to make room for a new patient; it was La Garde who looked after the nurses, brought help to the operating-table, wrote prescriptions hurriedly, made a hundred suggestions, answered all questions, whose watchful eye saw everything, and who uncomplainingly made the most of the means at his command—the hospital was none too well equipped. . . . Assistants left this brave doctor; hard work, loss of sleep, the reek, the sights, and, finally, the yellow fever were too much for them; but he was enlisted for

the war and stayed to the end. It would have been morally impossible for Major La Garde to find an excuse for leaving his post. The writer last saw him on July 26th. The man was brain-fagged and spent from physical weariness. His step was not so quick and firm as it had been, but he was still game to the core, and there could be no doubt that he would be the last man to leave the hospital. . . . Shafter took Santiago; La Garde took men's hearts, and he will live in them. Duty was his beacon."

This war has demonstrated to an incredulous world that the American soldier is second to none in any of the qualities that make a warrior, and the members of the medical corps are second to none of their combatant comrades in any of the qualities that make a hero.

THE METRIC SYSTEM.

The metric system dates from the time of the French revolution. In 1789 the French national assembly determined to reform their weights and measures and enforce a uniform system throughout the country. At the same time, with the view of devising a system which should be adopted universally, they invited the other European nations to take part in a conference for the purpose of considering the matter. England alone of the nations refused to be represented at the conference.

At the present time the metric system is in use for all purposes by all the civilized nations, with the exception of England, Russia, and the United States. Here its use is optional, and in Russia it will soon be obligatory. It is argued by some that, as our commerce, exports, and imports with the United Kingdom amount to much more than with all other European countries put together, therefore we and England should not be dictated to as to what methods of measurement we are to use, but rather are in a position to dictate to the world. However, this argument will hardly hold water, as it has been conclusively shown that a large amount of trouble, not to speak of risk of error in calculation, would be avoided by the adoption of the decimal system. Undoubtedly the change would occasion some temporary inconvenience, but this would in the long run be more than counterbalanced by the benefits resulting from it. Happily there is evidence in both countries that both scientific and business men are becoming convinced of the superiority of the metric system, and it is probable that ere long it will be in force in all parts of the civilized world. The International Railway Congress, at its session held in London, June to July, 1895, adopted the following resolution: "The congress expresses a unanimous desire that those countries which hitherto have not employed the decimal system should make every effort to adopt the metric system as soon as possible for their weights and measures."

In the revised edition of the British Pharmacopœia, recently published, the members of the council have done their best to hasten the adoption of the metric system by using both systems. One thing is certain, that if either this country or the United Kingdom decides upon the enforcement of the decimal system the other country will be compelled to follow suit. Why should not America lead the way?

News of the Week.

A Conference of State and Provincial Boards of Health of North America was opened at Detroit on August 10th. On the day preceding the opening there was a meeting held in celebration of the quarter-centennial of the Michigan State board of health, at which many congratulatory addresses were made by visiting sanitarians, of whom nearly one hundred were present.

Dr. John McG. Woodbury, of New York, has been appointed by General Wilson, the military governor of Porto Rico, chief surgeon of the sanitary corps for the island. Dr. Woodbury was on General Wilson's staff previous to his appointment as chief sanitary officer.

Prof. E. v. Leyden, of Berlin, was recently elected corresponding member in the section of medicine and surgery of the Academy of Sciences of Paris.

The Canadian Medical Association will hold its thirty-first annual meeting in the reception hall of Laval University, Quebec, on August 17th, 18th, and 19th, under the presidency of Dr. J. M. Beausoleil. The preliminary programme contains the titles of twenty-four papers which are to be presented during the meeting.

The White Cross Mission is the name of a new society recently organized in Oregon. It is similar in character to the Red Cross Society, and with the permission of the war department will begin its work of nursing at Manila.

The Philadelphia Pathological Society.—Drs. William H. Welch, of Baltimore, M. V. Cornil, of Paris, and R. Virchow, of Berlin, were recently elected corresponding members of the Pathological Society of Philadelphia.

Dr. Pepper's Will.—Contrary to expectation, Dr. Pepper, whose will was probated in Philadelphia on August 9th, left no public bequests. The document provided for a gift of $75,000 to the University of Pennsylvania, but a codicil revoked this bequest, with the explanation that the gift was made during Dr. Pepper's lifetime.

Survival from an Electric Shock.—An employee of one of the underground trolley roads in this city apparently received a discharge of two thousand volts through his arms a few days ago and was not killed. He entered the conduit through a manhole in order to remedy some defect, but while climbing out after completing his task accidentally placed both hands on the channel rail. He was instantly rendered unconscious and was picked up apparently dead, but soon revived and had only some severe burns on the hands to remind him of his carelessness. The full strength of the current was two thousand volts.

Veterinary Study in Massachusetts.—The last legislature of Massachusetts appropriated $25,000 for the erection and equipment of a veterinary laboratory and stable hospital in connection with the State Agricultural College. Provision was also made for an annual appropriation of $1,000 as a maintenance fund for the veterinary laboratory, to provide means of instruction, and to carry on investigations of the diseases of domestic animals. This allowance is to be made from January 1, 1899. Two new buildings are to be erected. One will be used as a hospital, and the other will contain the class-rooms for students in veterinary science, the private office of the professor in the department, his cabinet of specimens, and other rooms connected with the work. The cabinet will open into the laboratory, so that the specimens can be used for either class-room or laboratory work. The Agricultural College, although giving a thorough preliminary course in veterinary medicine, does not grant any degree. Those who wish for this must take the regular courses in professional veterinary schools.

A Polish Medical Congress.—Preparations have been making for several months to hold a congress of medical men from Russian, Austrian, and Prussian Poland. The meeting was to have been held this summer at Posen, but now the Prussian government has forbidden it, through fear that it would serve as an occasion for a Pan-Slavic propaganda, which would be highly disagreeable to both Austria and Prussia.

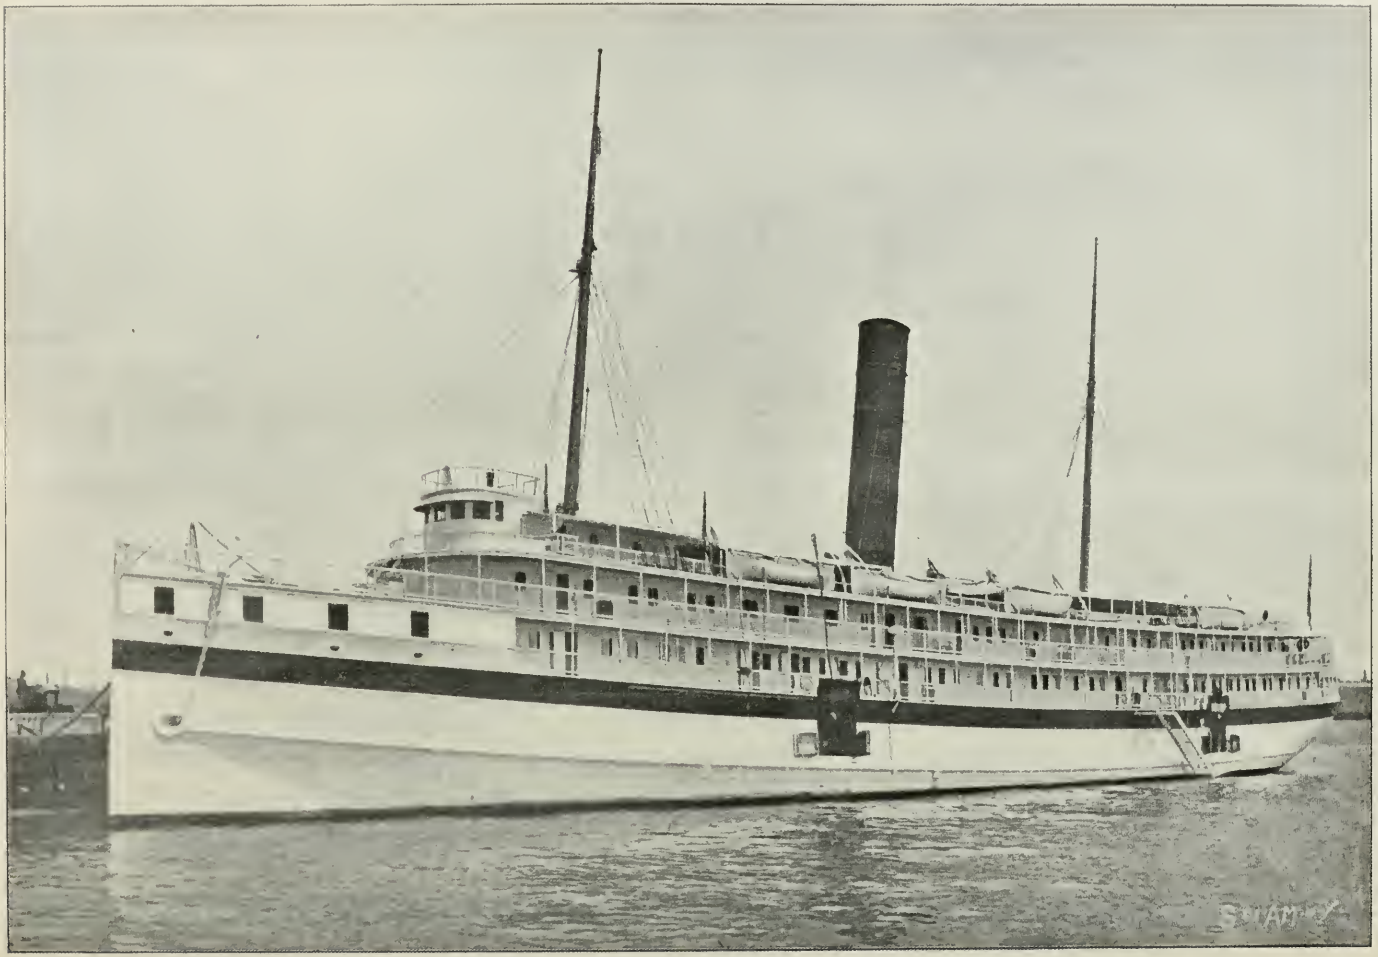
Artificial Albumin.—It is reported that a Dr. Lilienfeld, of Vienna, has discovered a process for making albumin artificially out of certain coal-tar waste products. He claims that it has all the properties of peptone, and that by means of it one can obtain albumin in sufficient quantity to support life at an expenditure of about eight cents a day. It occurs in the form of a brown powder and has a taste resembling egg albumen.

Obituary Notes.—Dr. Richard M. Swearingen, of Austin, Tex., died suddenly on Sunday, August 7th. He was born nearly sixty years ago, and obtained his medical degree from the New Orleans School of Medicine in 1867 and from the Louisville Medical College in 1886. Dr. Swearingen was State health officer of Texas for twelve years, and rendered most efficient service on several occasions, notably during the yellow-fever outbreak on the Gulf coast in the autumn of 1897. At this time he sustained Dr. Guitéras in his diagnosis of yellow fever in Galveston and other places, and for this was most severely criticised by many of the medical profession as well as of the business community in the infected places. He was a member of a number of medical organizations, and had served a term as president of the Texas State Medical Society.—Dr. John H. Pickett, of Elizabeth, N. J., died on August 9th, after a long illness. He was born in New York about seventy years ago, and was a graduate in medicine of the University of Buffalo, medical department, in 1860. He served as surgeon in the civil war, receiving a medal for important services at Gettysburg, and at the close of the war settled in Elizabeth, where he had for many years an extensive practice. He leaves a widow.—Dr. Thomas J. Doughty, of Fishkill, N. Y., died at the residence of his father, Dr. John H. Doughty, in Matteawan, on August 2d. He was born at Poughquag, Dutchess County, in 1865, and was graduated in medicine from the University of Michigan in the class of 1896. He had practised in Fishkill since his graduation, and was health officer for the town of Fishkill and the village of Matteawan.—Dr. Carl E. Elsner, of New York, died at his home, on August 8th, after a lingering illness. He was born in Germany, and received his medical degree from the University of Halle in 1874. He came to this country about twenty years ago.—Dr. Warren Kemble, of Saugerties, N. Y., one of the most prominent physicians of Ulster County, died on August 10th, at the age of fifty-seven years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1868.

Dr. A. Monae Lesser, of the Red Cross, who was sent North on the *Concho*, and, though ill, was forced to take care of the sick and wounded because there was no other surgeon on board, has been seriously ill since his return. We are glad to learn, however, that he is now rapidly convalescing.

The Camp at Montauk Point.—A new camp has been established at Montauk Point to receive the fever-stricken troops from Santiago, some of whom have already arrived, while others are on the way. Some difficulty has been experienced in getting water, because of the presence of large boulders that interfere with digging or drilling, but otherwise the site is admirably adapted for its purpose. The general hospital for the camp is said to be one of the most complete of its kind ever constructed. There is one central covered passageway, and at the sea end of this are the quarters of the surgeons attached to the hospital and the division surgeons. Near by is the operating-tent and the tent for the storage of hospital supplies. From the covered passageway range sixteen rows of tents, containing five hundred cots. Other rows can be added should necessity arise. At the farthest part of the hospital camp are the kitchen and wash tents. Colonel Forwood is the surgeon in charge. Near the outskirts of the camp will be five detention hospitals, with two hundred and fifty beds. These will be used for detaining men who are brought in sick. As soon as the surgeons in charge are satisfied that the nature of the illness is not such as to make quarantine necessary, the men will be transferred to other quarters. In addition to the general hospital, each regiment will have its own hospital, which will be in charge of the regimental surgeon.

Transports under the Care of the Marine Hospital Service.—The secretary of war has issued an order placing all sanitary matters pertaining to the condition of transports and crews under the jurisdiction of medical officers of the United States Marine Hospital service. Every vessel engaged in the transport service between the United States and Cuban or Porto Rican ports is to carry a medical officer of the army or of the Marine Hospital service, whose duty shall be



that of sanitary inspector of the vessel, and who shall see that in a foreign port no material or person is taken aboard liable to convey yellow fever; he will also keep the crews of the transports under surveillance, and on the return voyage act as sanitary inspector. In his instructions to the sanitary inspectors, Surgeon-General Wyman says that if a transport brings back sick or wounded soldiers, the latter are under the care of the medical officer of the army detailed for this purpose. For their treatment, medical supplies, etc., the medical department of the United States army is responsible. If, however, an inspector is called on by the proper authority for assistance to the sick or wounded soldiers, he is authorized to render it. In absence of a medical officer of the army, he will render such assistance as may be possible. The inspectors are especially instructed to look carefully after the water supply on the transport. In order to obviate the necessity of a vexatious quarantine of transports containing sick or wounded soldiers, it has been determined to station a receiving-ship at all the principal ports in Cuba and Porto Rico for the reception of those intending to sail for this country. This ship will be practically a detention camp and quarantine station, and passengers seeking homeward voyage are to be taken from the receiving-ship after they have undergone a period of observation and after their baggage has been thoroughly disinfected. The troops sent north from Santiago are to be held under observation for from three to five days in a separate camp not infected with yellow fever. They must be bathed and their clothing and luggage are to be disinfected before they are permitted to embark.

The Health of the Navy.—In reply to an inquiry from the secretary of the navy, Admiral Sampson, on August 6th, telegraphed the following report of the health of the men in his fleet: "Marine battalion is in excellent health. Sick list numbers two and one-half per cent. Fleet surgeon reports that they are in better condition for service in this climate than they were when they first arrived South in June. Health of the squadron at Guantanamo fairly good. Sick list numbers about three per cent. General tone of health of the ships' companies has fallen considerably since the 1st of July. This, however, is not due to the prevalence of any disease, but is probably due to the release from the strain and constant effort under which they so long lived, and to this, probably more than to any other cause, is due their somewhat impaired physique. I do not think it necessary to send the marine battalion North. The crews have borne their privations in a manner beyond praise; those of three ships have not been ashore for seven months, and these months in a debilitating climate."

A Home for Convalescent Soldiers.—The park board of this city has offered the use of the West End Hotel, in Fort Washington Park, near Washington Heights, for convalescent soldiers. Fort Washington Park contains forty-one acres. The West End Hotel, which is offered for the use of the convalescent soldiers, faces the Hudson. It is a large brick hotel, surrounded with spacious piazzas, and is admirably adapted for the purpose suggested. A number of citizens in the neighborhood of the park have offered to furnish the hotel for the accommodation of the soldiers.

Gifts of Drinkables.—A well-known French wine house has presented to the medical department of the army twelve hundred bottles of extra dry champagne, and a German firm has made a donation of ten thousand bottles of a table water.

THE HOSPITAL SHIPS.

The accompanying excellent illustrations, depicting respectively a ward on the army hospital ship *Relief* and the operating-room on the naval hospital ship *Solace*, we are enabled to present to our readers through the courtesy of the proprietors of the *Scientific American*. In recent numbers of the Medical Record descriptive sketches have been given of these vessels, but it may be as well to recapitulate their more salient features.

The naval ship *Solace*, formerly the coasting steamship *Creole*, was the first to be fitted out and put in commission for hospital and ambulance purposes; closely followed, however, by the *Relief*. The *Solace* is 375 feet long, of 3,800 tons displacement, with a speed of about sixteen knots an hour. She has ample capacity for carrying a very large quantity of ship's stores, pantry supplies, medical, surgical, and hospital necessaries, and has a large sterilizing-plant. On the main deck are blowers for promoting artificial ventilation, quarters for the crew, hoisting engines, etc., and immediately abaft a large ward with berth and cot accommodations for one hundred patients. Well aft is the emergency ward, with fifty swinging cots. Great care has been exercised to insure to the patients plenty of room, so that they may have the benefit of pure air. Between the berth decks are the laundry, drying, cold storage, and engine-rooms, the artificial ice plant, and quarters and messroom for apothecaries, petty officers, nurses, etc. Forward is the operating-room, tiled with interlocking rubber discs, with ceilings and bulkheads enamelled white. The operating-tables are of steel, also white enamelled. The illustration shows two operating-tables, a steam sterilizer immediately to the rear thereof, and the array of trays and shelves and cases for instruments and appliances on the right. Two steam launches, fitted with platforms for the accommodation of the ill or wounded, form a part of the ship's complement, together with a specially devised apparatus for hoisting or lowering the sick or wounded.

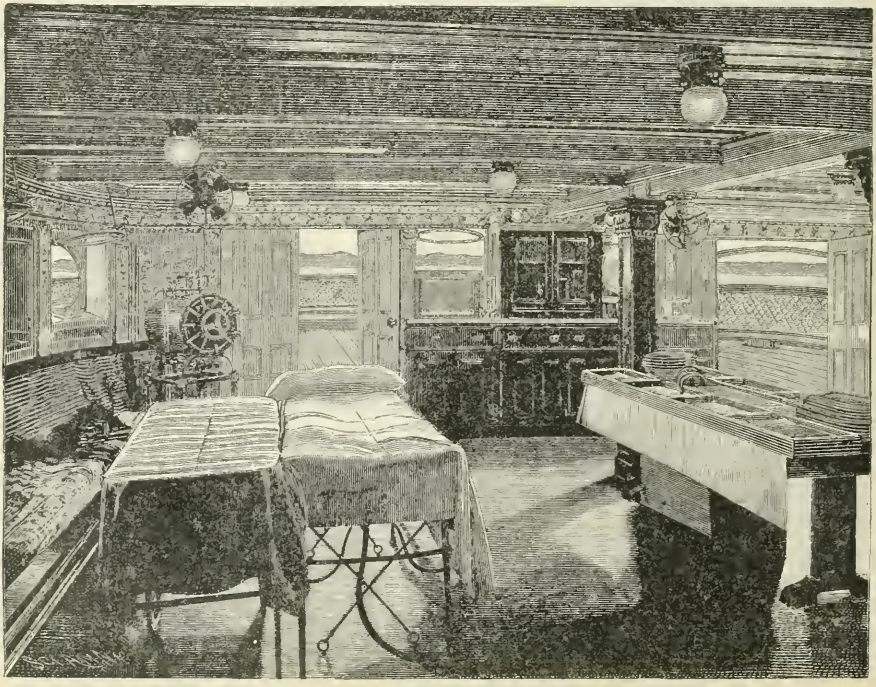
The *Relief* is somewhat shorter and slower than the *Solace*, and is of 3,500 tons displacement. She is divided into five wards for the accommodation of patients, the two largest of which are on the main and berth decks. Our illustration exhibits the one on the main deck. Each of these wards will accommodate about one hundred sick men. The general details of the *Solace* and *Relief* are practically identical, although probably the *Relief* is rather the better-equipped vessel of the two. Both ships are furnished with complete *x*-ray outfits, electric fans, refrigerating-plant, microscopic laboratory, photographic appliances, ice-making machine, and distilling-plant.

The medical staff of the *Solace* includes four naval surgeons, three naval apothecaries, and thirteen male nurses and attendants. On the *Relief* are eight army surgeons and hospital stewards, and sixteen nurses and attendants. The accommodation for patients on board the *Relief* is much more extensive than on the *Solace*.

MAIN DECK FORWARD WARD OF "RELIEF."

It is estimated that if necessary she could provide cots for nearly five hundred patients.

The United States have every reason to be proud of the *Solace* and *Relief*, and the only pity is that they had not more of the kind. The results of the Cuban expedition have clearly demonstrated the absolute need of properly equipped ambulance ships, so as to insure efficient medical treatment for the sick and wounded while on board, and a speedy and comfortable transit to their native land.



OPERATING-ROOM ON THE NAVAL HOSPITAL SHIP "SOLACE."

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-Sixth Annual Meeting, Held in Edinburgh, July 26, 27, 28, and 29, 1898.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

FOR the third time since its foundation, the British Medical Association met in Edinburgh, on July 26, 1898, in magnificent weather, in the ancient and beautiful capital of Scotland. Those members who arrived on Monday found the reception room open for their accommodation at the Odd Fellows' Hall, conveniently near to the Royal Infirmary and the new university buildings, in which most of the meetings take place. Between six and seven hundred members took out their tickets here during the day, and obtained information as to the many arrangements for the meetings, the entertainments, the excursions, and so forth. They then had time to visit the museums or other attractions of this city. A stroll through the Pathological Museum afforded an excellent preliminary to the other work in store. This fine collection was displayed in the dissecting-room of the university, and the exhibits were grouped under six headings. The committee very successfully aimed to illustrate the subjects which at present bulk largely in the minds of the profession, with special reference to such as form the basis of discussions and papers in the several sections of the present meeting. Altogether some two thousand specimens are exhibited. In the education section a series of casts and dissections from the surgical laboratory of the university, by Mr. H. J. Styles, aptly illustrate Professor Chiene's method of cerebral localization for operative purposes, and alongside these specimens there are numerous illustrative stereoscopic photographs. In this section also are specimens of the abdominal organs hardened by formalin, also the work of Mr. H. J. Styles; and a number of gelatin casts by the same gentleman and Mr. David Wallace, illustrative of surgical anatomy. Then there are specimens of Mr. Cathcart's method of making casts in glycerin, gelatin, and papier maché. Dr. Shennan shows specimens of Jore's formalin method of mounting, in which the natural colors are retained. Mr. James Simpson has some ingeniously mounted specimens for museum purposes, with the history of each case and its microscopic structure. Close by is a stand for showing the human skull in a natural position, the bones of Sir Walter Scott's "Black Dwarf," and the skin of a tattooed man. Then there are some very fine blotting-paper models by Mitchell Caird. Dr. Peters shows some remarkably delicate plaster casts. He sprays melted paraffin wax with a powerful blast on to the subject, alive or dead, and then backs it with gypsum. The results are remarkably fine, and the method is said to be easier than that usually employed. There is a dissected dead rabbit with all the viscera displayed, and the head of Dr. Harvey Littlejohn, who is happily still alive and can therefore examine this fine counterpart of himself. The parts are not flattened by the weight of the plaster, and the process is certain to be widely used.

In the surgical division there are forty specimens of elbow-joints operated upon by Professor Annandale, and twenty-four specimens of knee-joints, and about as many of intestinal surgery. Close by Mr. Alexander Miles exhibits interesting specimens of the skull and brain, showing the effects of severe injuries. The bacteriological series is very full and instructive, and is largely indebted to Drs. Robert Muir and Shennan. Dr. Sims Woodhead has sent a number of small animals—white mice, guinea-pigs, etc.—illustrating the effects of inoculating tuberculosis.

In the medical series Dr. Byrom Bramwell shows the original water-colored drawings and photographs which were done for his splendid atlas, and Dr. Allan Jamieson a number of drawings of rare skin diseases. There are many specimens of cerebral tumors exhibited by Drs. Bruce, Murray, and George Richardson. Another attractive exhibit is a fine series of eyes, mounted in gelatin jelly, by Drs. M'Gillivray, Paterson, McKay, and Buchanan. A collection of more than thirty skulls, showing the variations in the frontal sinuses, is by Dr. Logan Turner. Round the room are about one hundred and fifty microscopes with slides illustrating modern pathology.

The committee has also found room for the exhibition of some curiosities, such as the dissecting-case which John Goodsir used at his lectures and demonstrations; John Hunter's writing-desk and the boiler in which he boiled the body of O'Brien, the Irish giant; a post-mortem table from the old Royal Infirmary; John Knox's dissecting-table and surgical instruments, which once belonged to Liston, Miller, and Spence.

First Day—Tuesday, July 26th.

In the morning a preliminary service of greeting was held in the historic Cathedral of St. Giles, where the leading men of the several denominations met to welcome the association. The Very Rev. J. Cameron Lees, D.D., LL.D., dean of the Order of the Thistle and of the Chapel Royal, and chaplain to her Majesty the Queen, was to have opened the proceedings, but was unfortunately prevented by indisposition from attending; but his place was ably filled by the REV. WELLWOOD LANE, one of the assistant clergy of the cathedral.

The RIGHT REV. WILLIAM BLAIR, D.D., moderator of the United Presbyterian Church of Scotland, read the lesson of the day, 1 Cor. xiii.; and an address on Sir Thomas Browne was delivered by the RIGHT REV. ALEXANDER WHYTE, D.D., moderator of the Free Church of Scotland, who pronounced an eloquent eulogium upon the author of "Religio Medici," the extraordinary depth of whose language and the richness and imaginative sweep of whose mind, no less than his rare wisdom and wealth of heart, and his quite wonderful English style—all combined to seal Sir Thomas Browne with his well-earned reputation. Having glanced at the life of his subject as it appeared to himself and others, the right reverend moderator proceeded to consider Sir Thomas as an author, and said that his other works acquired their value and took their rank just according to the degree of their affinity to the "Religio Medici." Properly to understand this wonderful book, it must be opened and studied honestly and devoutly, especially if any gain and enjoyment were to be derived from its perusal. "I am a medical man," said Sir Thomas Browne, in introducing himself to us, "and this is my religion. I am a physician, and this is my faith, and my morals, and my whole true and proper life. The scandal of my profession, the natural course of my studies, and the indifference of my behavior and discourse in matters of religion might persuade the world that I had no religion at all. And yet, in despite of all that, I dare, without usurpation, assume the honorable style of a Christian."

The speaker then went on to say that the author of "Religio Medici" was never angry with any one, even his enemy, and, while preferring the Church of England, never unchurched or ostracized any man, and had no genius for religious disputes. On the subject of

admirers, Dr. Whyte said that Samuel Johnson, Coleridge, Thomas Carlyle, Hazlitt, and Lytton were among them; also Pater, Leslie Stephen, and Saintsbury, than whom no one had written more appreciatively of Sir Thomas Browne, who had also many editors and annotators, among others Sir Kenelm Digby, Simon Wickin, Dr. Greenhill, and Dr. Lloyd Roberts. In conclusion, he alluded to Browne's imagination and faith, and his nobility and purity of mind. Up through "all the weeds and tares of his brain," as Sir Thomas himself calls them, his imagination and his faith shot and sprang and spread, till they covered with their finest fruits the whole mind and heart and life. Sir Thomas Browne was a noble illustration of Bacon's noble law; for he carried all his studies, experiments, and operations to such a depth in his own mind and heart and imagination, that he was able to testify to all his fellow-physicians that he who studies men and medicine deeply enough will meet with as many intellectual and scientific and religious adventures every day as any traveller will meet with in Africa itself. Browne never wrote a single line, even in the greenest studies, that on his deathbed he desired to blot out. A purer, more humble, more devout hand never put English pen to paper than was the hand of Sir Thomas Browne. And if even in his greener days he had a doubt about any truth of natural or revealed religion, he tells us that he had fought down every such thought in his closet and on his knees.

The fine old church, which contains some beautiful stained glass and many famous old regimental colors, was filled throughout by a large and attentive audience, including a number of ladies; the congregation appeared to appreciate and in many cases heartily participate in the simple service, which concluded with the apostolic benediction.

The first general meeting was held at the McEwan Hall in the afternoon, and was well attended, a remarkable feature of the meeting being that many of those composing it were ladies, who seemed to take a lively interest in the proceedings. The lord provost, magistrates, and town councillors, in their robes of office, added a novel feature to the proceedings, the lord provost occupying a seat on the right of the president's chair.

After the adoption of the minutes, the retiring president, Dr. Roddick, of Montreal, said that it was his pleasing duty to relinquish his position in favor of Sir Thomas Grainger Stewart, who needed no other introduction from him (Dr. Roddick) to those present than the mention of his honored name. His reputation was world wide, both as a skilful physician and as an able and attractive teacher. In Canada the name of Sir Thomas Grainger Stewart was a household word, he having had to do more or less directly with the training of the more eminent physicians and doctors in the dominion than perhaps any other teacher living.

He congratulated the association on meeting on this occasion in the beautiful city of Edinburgh, the Modern Athens, and he also congratulated himself on the opportunity that had been afforded of handing over his office to so distinguished a successor. [Applause.]

Sir Thomas Grainger Stewart, having taken the chair amid renewed applause, called upon the lord provost to bid the association welcome.

The Lord Provost, who was attired in his gorgeous robes of office, was very cordially received, and said that on behalf of the municipality and the inhabitants of Edinburgh he had great pleasure in offering a most cordial welcome to the British Medical Association, embracing as it did representatives of the medical profession from all parts of the United Kingdom and the colonies, to the capital of Scotland. He was sure that no one would for a moment think that he said this in a boastful spirit, but the association could not have selected a more suitable place for its deliberations, for, apart from its beauty and its many historical associations, Edinburgh possessed one of the most important medical schools in the world. It might interest the association to know that the town council had a large share in the patronage of the university chairs, and when he told them that at one time when it was sole patron it elected such men as Christison, Allison, Playfair, Simpson, Bennet, and Haycock, he was sure the members would agree that it exercised its privileges with discretion and wisdom.

The medical school of Edinburgh still held a prominent position, and that to a large extent was due to the men in whose hands was the present teaching of the students. It was a thankless task to single out names, but he was sure that his brethren in the profession would understand him (the lord provost) and join with him in saying that the inhabitants of Scotland received with the liveliest satisfaction the news that the General Medical Council had conferred the blue ribbon of the profession upon their townsman, Sir William Turner. His lordship then referred to the fact that recently the freedom of the city had been conferred upon Lord Lister, and went on to say that the selection of a president of the association, so well known and so highly respected as Sir Thomas Grainger Stewart, was most gratifying. He hoped that under Sir Thomas' presidency its meetings would tend to the advancement of medical science, and that the interchange of thought and opinions among the members would have a soothing and healing effect on human suffering. The medical was a noble profession, and their reward was the satisfaction of knowing that their lives and work were given for the alleviation of the miseries of mankind. He concluded by once more offering them a cordial welcome to the city of Edinburgh. [Applause.]

The lord provost and council then withdrew. On the motion of the chairman; the thanks of the meeting were given to Dr. Roddick, the first colonial president, who was elected a vice-president of the association for life.

Honorary Members.—The president of the council, Dr. Saundby, then said that the success of the meeting of the association in Montreal was largely due to the governor-general (the Earl of Aberdeen) and the high commissioner for Canada (Lord Strathcona and Mount Royal), and to show its gratitude the council recommended that both gentlemen should be elected honorary members. The council also recommended the election of Prof. Francesco Durante, the eminent Italian surgeon, as an honorary member; and all three were duly elected accordingly amid much cheering.

Annual Report.—This was on the whole satisfactory, mention being made that this was the association's third visit to Edinburgh, the high position the city occupied in the medical world fully entitling it to the honor. The revenue of the year had been £40,443, while the expenditure had been £36,973, leaving a surplus of £3,470. During the year premises had been purchased at the corner of Agar Street and the Strand for £79,000, and the council now congratulated the association upon possessing a home worthy of its importance. In regard to the question of medical defence the council had taken an attitude of *non possumus*. It proposed to institute a scholarship in memory of the late editor, to be known as the Ernest Hart scholarship.

Medical Defence.—When the report was concluded much discussion, more or less heated, took place upon the question of medical defence, and several amendments were moved to that part of the report. Dr. James Myrtle (Harrogate) moved that the question of undertaking medical defence by the British Medical Association having been decided by a majority at for-

mer annual meetings, the council undertake to reconsider the report, with a view of bringing the question to a satisfactory issue. He contended that the council was wrong in counting as opposed to the proposal all those who had not returned post cards. He could equally well claim that their indifference showed they were in favor of it. [Laughter and applause.]

Dr. Jackson (Plymouth) said he could not understand why the council should say the majority were against the proposal, merely because the half of the members did not take the trouble to vote.

Mr. Victor Horsley said the question concerned the members of the United Kingdom alone, and the fact that sixty per cent. of these members voted in favor of the proposal was a sufficiently strong argument in favor of the council taking up the defence. He went further, and said that when they got that sixty per cent. to vote they got as many votes as they could expect. The profession had yet to be aroused upon that and other points. If the council had decided that it was unwise for the association to take up the question of defence, it should propose an alternative, such as subsidizing those who undertook the work.

Dr. John Haddon (Hawick) said the association was brought into existence for the advancement of medical science, and should have nothing to do with such a scheme as general medical defence.

Dr. Ward Cousins said there were great difficulties in the way of carrying out such a scheme as that proposed. He believed there was a large number of members in favor of it, but there was a still greater number who were opposed to it.

Dr. Woodcock said there were members of the council who thought that medical defence by the association was a desirable thing, if it could be done with safety, but in the face of the strong opposition they could not carry it out. Important branches, like that of Dublin, were strongly against it, and if it were carried they would have to face a revolt of that branch, and probably a secession. If it were attempted to go on with the scheme at the present time, the results in all probability would be most disastrous to the association.

Dr. Garret Horder said he was strongly of opinion that the majority of the members in general meeting assembled had given such an expression of opinion in favor of the proposal that the council should be encouraged and not discouraged in going on with the scheme.

Dr. Brassey Brierley also supported the amendment.

Mr. Muir (Glasgow) said that at a small meeting—thirty out of three hundred members—in the west of Scotland, there was a small majority against the proposal; but he wished to point out that the majority were consulting practitioners, to whom the question was of little or no importance. The minority were general practitioners, to whom it was simply vital.

Dr. Saundby, in replying on the discussion, said it was not because they did not think medical defence a good thing that they did not take it up, but because of the practical difficulties in the way. The council at a very large meeting unanimously approved of the report, and, no matter how the meeting voted, the council could hardly change its mind now. The remedy of the association, if they felt aggrieved, was to turn the present members out. [Cries of "Oh!"]

On a show of hands the amendment was defeated by one hundred and one votes to eighty-nine.

Loud cries of "Divide, divide!" were passed unheeded.

Reports of various committees were then formally submitted. On the report of the parliamentary-bills committee Dr. Brassey Brierley complained that the committee had not done anything with regard to the amending of the medical acts.

Dr. Saundby said they were sorry that the bill for the amendment of these acts was presented so late that it only came before the committee on July 5th, and the committee felt they could not do justice to so complicated a matter in the short time at their disposal.

Dr. Brierley expressed himself as satisfied with this explanation.

The meeting adjourned about five o'clock to meet again at half-past eight to listen to

The President's Inaugural Address.—There was a brilliant gathering at the adjourned general meeting in the evening to listen to the address. The magnificent hall was not crowded, but the area of the hall and the lower gallery were occupied by ladies and gentlemen in evening costume, while the upper gallery was allotted to students and others who were not members of the association, or were unable to appear in suitable attire. The organist to the university beguiled the time of waiting by a selection of music that was greatly appreciated. As the president made his progress up the hall he was loudly cheered, and among those who occupied seats on the platform were Dr. Roddick, who took the vice-chair; Dr. Saundby, chairman of the council of the association; Dr. Osler, of Baltimore; Dr. Farquharson, M.P.; Sir William Stokes, Sir Henry Littlejohn, Sir Robert Pullar, Dr. Bruce Goff, and others. The president proceeded at once to deliver his address (see page 203).

Professor Roddick, of Montreal, in moving a vote of thanks to the president for his very able and interesting address, said that it was just what was wanted, but that when he touched upon vaccination it was a sore point with them in Canada, where it and smallpox gave them more trouble than anything else. Some medical men, who, he was sorry to say, were French Canadians, had for several years carried on a crusade against vaccination and persuaded many of their countrymen from accepting the immunity it afforded against a most loathsome disease; but an epidemic broke out and many deaths followed—three or four thousand—and since then there had been no trouble about vaccination. He also thought it time that a great country like this should have a minister of public health, and if England did not hurry up in that respect Canada would soon be ahead of her.

Dr. Pavy, of London, seconded the vote of thanks in a neat little speech, and thought it was a great pity that there was not sufficient firmness of mind among Englishmen not to yield to the unbalanced minds of faddists. The freedom of the individual must yield for the benefit of the number.

The motion was put by Dr. Saundby and was carried by acclamation. The president bowed his acknowledgments.

The Royal Army Medical Corps.—A vote of thanks to Dr. Gordon for his work on the subcommittee on army medical reform was then moved by Mr. Macnamara, seconded by Dr. Farquharson, M.P., and cordially adopted. The speakers expressed satisfaction with the new warrant, and said the army service would henceforth afford an excellent career for earnest young surgeons.

The Lord Provost's Reception.—By this time every one was anxious to get away to the reception by the lord provost and Mrs. Mitchell Thomson, which was fixed for nine o'clock, but the guests began to assemble much earlier—some, it was said, arrived before eight—and there was a continuous stream of cabs and carriages toward the museum from that time until ten. Those who had attended the president's address walked to the door which was opened for their accommodation, but it was hardly wide enough at first, and for

a time there was a crush worthy of a royal drawing-room day. The museum is a kind of smaller South Kensington, and there was a great crowd. More than four thousand ladies and gentlemen were said to have attended. The lord provost, in his official robes, and Mrs. Thomson were attended by the sword and mace, the chief city officers, who announced the guests. The museum presented a brilliant spectacle, especially as seen from the galleries, where many took up a position to witness the ceremony of the official reception. After all had been announced, music was played by the band of the Royal Scots (late First Foot), familiarly known in the army as Pontius Pilate's body guard, on account of its antiquity. When the eleven pipers in full blast marched round the upper gallery, in which space had been reserved for them, an unappreciative Englishman whispered to your reporter that the Dumdum bullet is not the only "inhumane" implement (to quote Bruns) used against the gentle Afridi, and he quite understood the feelings which made them concentrate their fire on the pipers. Light refreshments were served at several tables. Outside the traffic was well regulated as the assembly broke up, and departing vehicles were heard until after midnight.

Second Day—Wednesday, July 27th.

There was a large attendance of members in McEwan Hall; the chair was occupied by Sir Thomas Grainger Stewart, the president of the association.

The Next Meeting.—Dr. Saundby intimated that at a meeting of the council, held that morning, it had been agreed to recommend that the invitation to hold the annual meeting of the association next year at Portsmouth should be accepted with thanks, and that Dr. Ward Cousins, of that town, should be appointed president-elect.

He moved the recommendation, and said there would be something appropriate in going from Edinburgh to the extreme south of England, which they had not visited for a number of years. Dr. Ward Cousins had been a very active member of the association, and it could not have a president who had done more to earn his position than he had.

The resolution was adopted, and Dr. Ward Cousins was congratulated by the president on his appointment.

Dr. Ward Cousins thanked the association for having accepted the invitation to Portsmouth. That town was, as they knew, a great naval and military centre, and he did not need to remind them that naval and military medical officers were warm friends of the association. [Applause.]

The Address in Medicine.—Dr. Thomas Richard Fraser, professor of materia medica and clinical medicine, University of Edinburgh, then delivered the annual address in medicine (see page 205).

Sir William Broadbent moved a vote of thanks to Professor Fraser for his able address; Prof. William Osler, of Baltimore, seconded. He said that Scotland had that combination of theory and practice which was needed in the medical profession. He felt that in some countries there was gradually arising a dissociation between theory and practice. The physiology that was taught in many eminent schools and the pharmacology taught in others often had not the direct and specific object of enabling the young men ultimately to cure disease. In Edinburgh they had a great advantage in having a man who was not only a laboratory worker, but also held a hospital position. Too many of them were too optimistic with regard to disease. There were plenty of diseases they would never cure, and it was lucky for the race they could never cure. Sir Thomas Browne, to whom they might go for occasional lessons in medicine as well as in morals, had pointed that out years ago.

The vote of thanks was carried by acclamation.

Some questions relating to proposed changes in the bylaws and the expenditure were then considered, and the proceedings terminated.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

First Day—Wednesday, July 27th.

The Teaching of Obstetrics.—Dr. A. R. Simpson, professor of midwifery and diseases of women and children at the University of Edinburgh, delivered the presidential address. He said that he was the occupant of the oldest chair of midwifery in the world, instituted by the town council of Edinburgh in 1726. The council resolved that the new professor should be "vested with the same privileges and immunities that are known to appertain to a professor of midwifery in any other well-regulated city or place:" but when one came to search for the privileged professor he was nowhere to be found. The chair of midwifery next in seniority was that of Strassburg, which was instituted two years later, in 1728. In that same year, Victor Amadeus II. of Piedmont started in Turin the first school for teaching midwifery, by setting apart a ward in the San Giovanni Hospital for Lying-in Women, where midwives should have practical instruction. This circumstance, that the first Italian obstetric clinic was provided for the teaching not of men but of women, suggested the reason why medicine and surgery had precedence of midwifery in the development of facilities for study in the respective departments. Through long ages the care of the lying-in woman had been consigned to members of her own sex, and the question of the propriety of allowing men to attend women in labor emerged in the seventeenth century only to give rise to bitter controversies, lasting until far on into the eighteenth. Even yet inadequate provision was made in medical curricula for the disciplining of students in this part of the healing art, although from the point of view of the legislator it took equal rank in importance with the other two great departments of medicine and surgery. If we had regard to the activities of the obstetrician as manifested in various relations, we would see that in none of them did he come behind the physician or the surgeon. If we looked to the journals that were open to the discussion of subjects in all branches of the profession, we could not fail to be impressed with the large space occupied by the papers on obstetrics and gynæcology. The speaker had occasion some years ago to look through a chance volume of the *Edinburgh Medical Journal*, and to note that the obstetric material amounted to more than a third of the whole—of the 630 pages occupied with original articles 233 being devoted to articles in this department. If we took the great "Sammlung klinischer Vorträge," we would find that important serial setting gynæcology on an equal plane with medicine and surgery. Perhaps this tendency to predominance of the gynæcological series might be due as much to the interest of the readers as to the productivity of the writers of the gynæcological literature.

This tendency to large development and diffusion of obstetric essays was not due to any special peculiarity in obstetric problems. The secret was to be found in the circumstance that a preponderating share of the best time and most anxious thought of the general practitioner was taken up with his obstetric cases.

The speaker once requested a country practitioner to look up the number of individual cases he had visited in the preceding month. These were 60 in number, and divided themselves into 11 men, 34 women (of whom 13 were general cases, 6 gynæcological, and

15 obstetric), and 15 children, besides again the 15 infants. Thus in this gentleman's practice fully a third were obstetric and gynæcological cases; and if were added the fifteen infants which he had learned in his midwifery course how to deal with, we would find that nearly one-half of the individuals under his care that month were dependent for their successful treatment on what he had been set in that class to learn. Young practitioners must learn that the successful conduct of confinements was the surest guarantee for speedy success in the career of an ordinary practitioner. Coming into a locality, a young doctor might get a reputation in the community for managing well an outbreak, say, of typhoid fever, or operating well in some case of injury. But his very triumph over the typhoid would be complete only when he had succeeded in preventing the possibility of its recurrence; and people would not be less careful to protect themselves from injuries though they knew they had a skilful surgeon near at hand. But each time it was whispered among the ladies that he was specially skilful in the handling of his confinement cases, the rumor of his skill and kindness must fall on the ear of some one who would say to herself: "My time is coming; I must have him to attend on me." It was the only gate into general practice that was always open everywhere.

The ordinary run of deliveries were cases of natural labor that might not call for active intervention, but at any moment emergencies might arise that would tax to the uttermost the practitioner's resourcefulness and self-reliance. If he had a case of heart or lung or brain disease that left him undecided when he saw it first as to what would be the best line of treatment, he could prescribe something that would be useful, or at least not hurtful, until on a second visit the course became more clear, or until he had had time to read up the subject in a system of medicine. But if a man came to a midwifery case and found an arm protruding, it was too late to think of reading up; if at the end of a labor that had gone on smoothly he found his patient becoming pale and pulseless, he had no time to get assistance. Before help could come the flooding might be fatal. If he was not to see the patient die before his eyes, he must recall the measures he had been taught to adopt in this contingency, and he must apply them with his own hands immediately. But how did this predominance of midwifery in practice look in comparison with the little time devoted to it in college study? The obstetric teacher, among a company of physicians and surgeons, was apt to find his subject regarded as a kind of subordinate specialty, which could be lectured on at any odd time to senior students, whose best hours were all laid out for them in the interests of systematic and clinical medicine and surgery, and their subsidiary branches. Dr. Simpson pleaded for greater recognition of the importance of midwifery study, and he said that every student should be drilled in the use of the various obstetric and gynæcological instruments and appliances; and especially he should be practised in the application of forceps and in the operation of version on the phantom. He ought to attend the clinics in a maternity hospital, since women were sent there because they were the subject of some difficulty or complication, which gave the teacher the opportunity of enforcing on the student the lessons of the didactic course, and showing him how abstract teaching was adapted to concrete cases.

A vote of thanks to the president for his address was proposed by Professor Playfair, and seconded by Professor Martin, of Berlin.

The Surgical Treatment of Pelvic Inflammation.—A discussion on this subject was opened by Dr. Cullingworth, of London. He commenced by stating that five years ago he drew attention to the backwardness of this country in the treatment of these diseases. More active treatment was now generally accepted, but there were some points still open to discussion. These points were: (1) Indications for operation in pelvic inflammation; (2) time to be chosen for operation; (3) methods of operation; (4) the extent of the principles of conservatism. In this paper he would deal with the first two only. The indications for operation were usually stated as (1) inflammation of the connective tissue, and (2) inflammation of the peritoneum.

As to pelvic cellulitis, there was a general agreement that when there was no suppuration no surgical treatment was needed. When there was suppuration the pus should be let out as soon as its presence was diagnosed, but always without opening the peritoneum, and generally by an incision above Poupart's ligament. When the pus was deeper an incision like that for tying the external iliac artery was suitable. A rarer situation for the pus was between the bladder and cervix. Still more rarely it passed through the sciatic notch into the loin, etc. Most cases which had been recorded as suppurating cellulitis in the upper parts of the broad ligament were really abscesses of the tube and ovary.

In pelvic peritonitis operative interference was not called for when the affection was due to simple catarrhal salpingitis, but it was called for when the presence of pus was diagnosed. It was not always easy to say when pus was present. The temperature was of little use as a guide. No absolute rules could be laid down, but the following were some points to guide in deciding on operative treatment: Operation was indicated after subsidence of the acute symptoms, when the bimanual examination showed a mass extending into the pouch of Douglas. In simple cases in which the mass was formed by a thickened tube, it was possible to trace the tube as a thick cord from the uterine cornu, but the outer extremity of the tube could seldom be defined. If, however, such swelling was larger than could be accounted for by the above condition, or if it was increasing, we were almost sure to find pus. If there was a tense globular cystic swelling bulging down into the vagina, there was probably an abscess. Operation was also indicated when there were outbreaks of recurrent pelvic peritonitis. Such attacks suggested the presence of pus, generally shut up in an ovary (abscess) or tube. Operation was demanded also when, with a lump in the pelvis, there were symptoms of general septic infection. In the speaker's own experience, such cases were generally of tubo-ovarian abscess due to the opening by ulceration of a pyosalpinx into an ovarian cyst. Sometimes when pus was not present, the swelling might enlarge and present fluctuation; it was then either a hydrosalpinx or a diseased ovary, and in either case it needed to be removed. Cystic disease of the ovary was so frequent an accompaniment of salpingitis as to suggest that the disease of the tube was a cause. Operation was also indicated, even when there was no sign of pus, in working-women who could not afford time for rest. In such cases the author considered an operation to be perfectly justified after matters had been explained to the patient.

As regarded the time for operation, general opinion was in favor of deferring operation until the acute symptoms of local pelvic peritonitis had subsided, because, in the first place, it was difficult to say whether pus was present or not. Secondly, the mortality was much greater when the patient was operated on while acute symptoms were present. Similar results were found in dealing with appendicitis; the peritoneum was much more tolerant after an attack of acute inflammation—which suggested immunity—and experiments on animals had shown the same thing. It had

been suggested that an injection of antistreptococcus serum into the peritoneal cavity be made on the day before the operation. A practical deduction was that the immunity passed off soon, and one should not postpone the operation too long after an acute attack had subsided.

Abdominal Hysterectomy and its Indication; Modification of the Technique of Vaginal Hysterectomy.—Dr. Doyen, of Paris, read a paper with this title. He said that he had been obliged to remove the uterus by vaginal hysterectomy in cases in which the adnexa had been removed by laparotomy, and now he often performed total ablation. Three operations might be performed per vaginam: (1) simple incision into the pus focus; (2) unilateral ablation of the adnexa; (3) total vaginal castration. In performing laparotomy, simple incision into the pus focus, he used the Trendelenburg position. The uterus should be removed when necessary. The vaginal method and laparotomy were not competing methods—each was suitable for its own class of cases. In his own method of performing vaginal hysterectomy, he crushed the broad ligaments with special forceps and left the forceps on for forty or fifty seconds. He closed the peritoneal cavity entirely.

Vaginal and Abdominal Way.—Dr. Jacobs, of Brussels, read a paper with this title. He used the opening by the vagina for ovarian abscess or pyosalpinx. Many patients were cured, but some relapsed and required further operation. The vaginal way was best for old-standing suppuration with fistulæ. He had used the vaginal way in 434 cases, with 8 deaths; the abdominal way in 95 cases, with 3 deaths. In the first series there were 5 cases of ureteral fistulæ and 2 of intestinal fistulæ. In old-standing cases of suppuration, he found that the pus was not virulent.

Vaginal Cœliotomy.—Dr. Landau, of Berlin, read this paper. He urged the importance in statistics of vaginal cœliotomy of stating for what the operation had been done. Many cases were only examined by the finger; in others the finger opened sacs and let out fluid, the origin of which alway remained a mystery. He gave statistics of his operations for the last three and a half years. In only one case was there perforation of the bladder; this was sutured and healed by first intention. The best results oftentimes ensued when least was done. Vaginal cœliotomy was indicated only when cœliotomy of any kind was indicated. The advantages were (1) that the peritoneum and intestines were not exposed, and (2) that the cicatrix was out of sight. He had known of two cases in which the scar yielded. The disadvantages were that it was impossible to introduce the hand; only two fingers could be used, and only the organs within reach of the finger could be dealt with. He would exclude from this operation all tumors which must not be ruptured in removal, and he would never perform it when ascites coexisted or when there was a suspicion of malignancy. The conditions for which he would perform it were the following: (1) For plastic operations on normal-sized uterus or ovaries; (2) for the removal of myomata up to the size of a child's head; (3) for the removal of ovarian tumors. The size of a tumor, if unilocular, was immaterial. He would never remove a papilloma by this method. Dermoids were not adapted for this method, as the contents were injurious to the peritoneum. Extra-uterine pregnancy was adapted for this method except when it had ruptured and was complicated by inflammation. He did not advocate extirpation of inflamed appendages by it, or its use when there was evidence of inflammation. It did not matter if it should become necessary to open from above to complete the operation, and it was better to do so than to persist on principle.

Dr. Sänger, of Leipsic, said that when it was possible to preserve one ovary or tube, he would do so. Professional opinion was going back to abdominal operation for complete removal in cases of suppuration and was against the use of clamps. He pointed out the frequency of appendicitis complicating inflammation of the appendages. He strongly advocated the Mikulicz method of drainage.

Dr. Fehling, of Halle, said that in doubtful cases he would make a puncture with the Dieulafoy aspirator. He always completed the operation by closing the peritoneum. He thought that when one appendage was affected, the Germans had been too radical in their procedures, but now they were tending the other way. In cases in which diagnosis was doubtful the abdominal way was better, as it gave more opportunity for inspecting the appendages. He protested against the practice of removing the uterus and leaving one ovary.

Dr. Martin, of Berlin, said that, in considering the question of operation, he made a point of inquiring carefully into the history, for if that led one to suppose that the condition was due to gonorrhœa the treatment was different from that required when it was due to sepsis. When it was due to gonorrhœa, he felt bound to adopt expectant treatment; when due to sepsis, it was less liable to be benefited by medical treatment. There was sometimes much difficulty in differentiating inflammatory conditions from extra-uterine pregnancy. In numerous cases in which the gonococci or other cocci were supposed to be the cause of the condition he had found extra-uterine pregnancy. He was doubtful whether it was necessary to remove the product of conception in all these cases when the fœtus was dead. One cause of these inflammatory conditions not commonly recognized was infection by the bacterium coli. This occurred especially in young girls suffering from chronic constipation. Menstruation began, attended by feverish disease, by and by swelling of adnexa; and when finally operation was done, infection with bacterium coli, either through adhesions or through lymphatics, was found. He recognized the necessity of operating early in poor people. In the technique it was very important to preserve the uterus, and if it gave rise to trouble it could be removed later. He did not now use drainage.

Dr. McCann, of London, delayed operation until he found it absolutely necessary. He thought that we ought to adopt the foreign method of making the bimanual examination with the patient on her back, using the right hand for examining the right side of the pelvis and the left hand for the left side.

Dr. Byers, of Belfast, said that there were many cases in which the question of pus could not be settled until the abdomen was opened. He thought that the vaginal method was especially suitable for cases in which women with pus in the pelvis came in an extremely exhausted condition; he quite agreed with previous speakers that operation in cases of acute peritonitis was very dangerous.

Dr. Ward Cousins, of Portsmouth, said that when the tumor impinged on the rectum he opened through the rectum. He had treated large numbers of cases of gonorrhœa in the Lock wards of Portsmouth Hospital, and had not found any which required operation.

Dr. Taylor Young, of Sydney, thought that the dorsal position should be used in conducting an examination.

Dr. Lapthorn Smith, of Montreal, agreed with Dr. Cullingworth as to the immunity conferred by an attack of peritonitis, and cases in which there had been several attacks did better than those in which there had been only one. He had just returned from a visit to the continent, and had seen the practice of many of the celebrated surgeons of Europe. As a result of his observation, he would lay down the rule that all large

tumors, pus tubes large and high up, hydrosalpinx, tubal pregnancy, should be removed by abdominal section. The operation of vaginal cœliotomy was suited to the removal of small tumors, cystic and cirrhotic ovaries, and for the treatment of retroversion with fixation. As regarded the question of removing the uterus, he would remove it if both ovaries and pus tubes were removed. He had given up drainage.

Dr. Amand Routh, of London, said that in cases of parametritis when the presence of pus was suspected, he used the aspirator and then incised and kept the opening from closing by using a diverging stem pessary.

Dr. Aust Lawrence, of Bristol, said he considered persistent diarrhœa a sign of dangerous sepsis.

Dr. Cullingworth, in closing, said he quite agreed with Professor Martin that in cases of gonorrhœa the probabilities were greatly in favor of resolution as compared with cases due to a septic cause. He also agreed as to infection by the bacterium coli, and he thought that the profession was not alive to the importance of keeping the bowels cleansed in these cases. He urged strongly the importance of diagnosis, and of comparing what we diagnosed with what we found at the operation. He always used and taught the method of bimanual examination with the patient on her back. The abscess in cases of acute pelvic suppuration frequently burst into the rectum, but not often into the bladder.

———

Second Day—Thursday, July 28th.

The proceedings on this day were marked by a very large attendance and characterized by much animation.

The Use and Abuse of the Midwifery Forceps.—Dr. Milne Murray, of Edinburgh, opened the discussion on this topic. He said that Baudelocque had remarked that the midwifery forceps were the most valuable surgical instrument ever invented, but to justify this praise it must be shown that the forceps diminished suffering and saved the life of both mother and child. The following were the indications which he laid down for the use of the forceps: Generally, when their use was better for both mother and child than non-interference; this aphorism should be more generally adhered to. No strict rules could be laid down, but it must be left to individual judgment. There were certain common errors in the use of the forceps, some due to lack of judgment as to when to use and when not. But this was not all; many injurious results were due to faulty technique. He would sum up in this way: Forceps were often used at the wrong time, sometimes not used at the right time, and frequently badly used. The dangers were: (1) laceration; (2) too sudden emptying of the uterus; (3) injury to the fœtal head. He thought that the greatest abuse of the forceps arose in connection with their application when the os was small. He recognized a special form of undilated os; this occurred when the woman had been in labor for some hours; examination in the absence of a pain showed that the os was soft and apparently dilatable, and that the head was low down; if the forceps were applied and the woman was then examined during a pain, the os was found to be tight and only half open. This condition the speaker denominated "spasmodic undilated os." On account of the thinness of the edge in such cases the cervix was easily lacerated. In the cases in which forceps were not used when they ought to be, vesico-vaginal fistula resulted, but this was now rare. He thought that a reaction was now showing itself against the frequent use of the forceps, and he feared that our vigilance in seizing the right time for their use might be relaxed. In the last report of the Rotunda Hospital it was stated that in forty-five cases forceps were used in the second stage after four hours' delay; he objected to this as giving the impression that time was the main factor in deciding on the use of the forceps. He would enunciate the following aphorism: "Wait till you see what nature can effect, not what she can endure."

In occipito-posterior positions when flexion was deficient, he thought that the sooner forceps were applied after the os was dilated the better; he had no faith in manual rotation. Forceps were abused by being badly used, through faults of technique, in not employing the most efficient instrument. The principle of axis traction, first introduced by Tarnier, was now always taught in the Edinburgh school, and the speaker thought that axis-traction forceps were superior at all stages of labor; they did not compress the head as much as ordinary forceps. He never removed the forceps before completing labor, and believed that under deep anæsthesia the use of axis-traction forceps saved the perineum. It was still the teaching of British schools that the forceps should be applied at the sides of the pelvis, but he held that they should be applied to the biparietal diameter, however the head might be placed. In the final stage of extraction he held the forceps with his right hand, pressing with his left hand on the uterus, and exerted traction as far as possible only during the pains; but he made an exception in certain cases in which each pain was accompanied by spasm of the vulvar orifice; in these he extracted under chloroform in the intervals of the pains.

Dr. Playfair, of London, thought that Dr. Japp Sinclair's address at Montreal had done good, but he did not agree with all that was said on that occasion, and he altogether denied the truth of the statement that the obstetrician furnished most of the material for the work of the surgical gynæcologist. The objection of improper use applied to all innovations in treatment. The case of the Princess Charlotte bore eloquent testimony to the badness of the practice of delay when the head was low down; in her case the fatal result was brought about by allowing the head to remain on the perineum for forty-eight hours, when forceps should have been used long before. A great gain in modern practice was the almost total abolition of craniotomy, and to this Dr. Sinclair did not allude in the address mentioned.

Dr. Smyly, of Dublin, said that in the Rotunda Hospital, while he was master, they always used axis-traction forceps at all stages of labor. He said that before it was allowable to use the forceps the head should be presenting and partially engaged in the brim, the os should be dilated, and the membranes should have been ruptured. When the forceps were applied above the brim we might not be able to deliver in certain cases in which, if we had had patience, nature might have accomplished delivery; the speaker attached very great importance in these cases to the moulding which took place. The explanation of the four hours' limit to which Dr. Milne Murray had referred was that that was the time fixed by the rules within which the student was to send for assistance, in the second stage. The statistics of the Rotunda for the seven years while he was master were 269 forceps deliveries out of 8,000 cases, or 1 in 33.

Dr. Fehling, of Halle, thought that we ought to teach students very carefully when to use the forceps, as the tendency of young obstetricians was always to use them too often. He still used the old form without axis traction. He would lay down as a rule that at least one-half of the head should have entered the brim before forceps might be applied. Dr. Cullingworth had shown that puerperal fever in private practice had not diminished, and Hegar had stated the same thing; the speaker thought that this might be due to our plac-

ing too much reliance upon antiseptics, and so becoming careless about the infliction of injuries and lacerations. He would apply the forceps at the side of the pelvis, and thought that by endeavoring to put them on in other positions lacerations were caused. His statistics showed about one in thirty forceps deliveries.

Sir William Priestley, of London, said that he had no doubt more children were saved and fewer mothers injured now than when he began the teaching of midwifery fifty years ago. Nevertheless he had seen very serious damage caused by the application of the forceps when the head was above the brim and the os was undilated.

Dr. Stephenson, of Aberdeen, laid down the axiom that artificial extraction must never derange the mechanism of nature.

Dr. Macan, of Dublin, taught the use of the ordinary long forceps as axis-traction forceps by applying both hands and pulling in such a way that the line of traction was parallel with the blades.

Dr. Byers, of Belfast, pointed out that cases were met with in which the rule of waiting for dilatation of the os before applying forceps must be broken; such were cases of eclampsia and of labor in aged primiparæ. In cases of flat pelvis he had obtained better results by the application of forceps at the brim than by version. He completed labor without removing the forceps.

Dr. Japp Sinclair, of Manchester, wished to deny emphatically that he had ever advocated a return to the old bad practice of leaving women in the second stage of labor when they ought to be delivered by forceps. The lesions to which he had alluded in his address were most frequently met with in the out-patient room.

Dr. Milne Murray, in closing, maintained that flexion was favored by axis-traction forceps.

One Hundred and Ninety-Eight Cases of Induced Premature Labor.—Dr. John Moir, of Edinburgh, who, the president announced, was in the ninety-fourth year of his age, read a paper with this title. The method which he adopted was the use of a blunt-pointed metal bougie of the thickness of one's finger; he passed this through the os and separated the membranes all round. In most cases labor ensued within a few days; if it did not, he followed this up by puncture of the membranes.

Missed Labor.—Dr. Mary Scharlieb, of London, reported a case of missed labor verified by operation and also post mortem. The woman expected her confinement in July, 1895, but no labor ensued; in September following there were pains and vaginal hemorrhage. On admission to the hospital in that month the patient was very ill, had fever, sordes on the lips, etc.; the abdomen was enlarged, but no fœtal heart sounds or movements were perceptible. Extra-uterine pregnancy was diagnosed. The operation was performed on September 28th. When the woman was under anæsthesia the fœtal parts could be felt through the abdominal walls. The uterus was opened in the middle line, and fetid fluid escaped. A macerated fœtus, weighing twelve pounds, was removed. The uterus, which was friable, was amputated low down. The patient died twenty-eight days after the operation. Careful examination of the uterus and appendages proved conclusively that gestation was intra-uterine.

Aseptic Midwifery.—Dr. Jardine, of Glasgow, read a paper with this title. After stating his opinion that all cases of puerperal sepsis were due to infection from without, with the single exception of those caused by the existence and bursting of a pelvic abscess, he laid stress on the following points in prevention: Careful cleansing of vulva and surrounding skin, done by the accoucheur himself; avoidance of examination under the clothes, as so often done; careful toilet of the vulva, after delivery, by the accoucheur himself. The speaker did not believe in routine douching in normal cases. In the puerperium he advised frequent cleansing of the genitals and sitting up of the woman in bed on the third day in order to facilitate escape of the discharges. The catheter should always be passed by sight and not by touch.

(To be Continued.)

AMERICAN ORTHOPEDIC ASSOCIATION.

Twelfth Annual Meeting, Held in Boston, Mass., May 17, 18, and 19, 1898.

Robert W. Lovett, M.D., of Boston, President.

First Day—Tuesday, May 17th.

President's Address.—Dr. Robert W. Lovett, of Boston, delivered this address. He said that the transactions of this association now constituted modern American orthopædic literature, and that, one after the other, the medical schools were announcing systematic instruction in orthopædic surgery. While it was natural that the first efforts of the association should have been toward the better management of the more common deformities, it was time now that the members gave more of their time to studying the pathological side of their specialty. No important additions had been made for many years to the pathology of hip disease, and next to nothing was known concerning this phase of acetabular disease. In his opinion, the good results that had been secured in the treatment of clubfoot were largely due to a clearer knowledge of its symptomatology and pathology. A more exact working basis, founded on a better pathological knowledge, would both dignify and broaden orthopædic surgery.

Traumatism of the Spine Simulating Pott's Disease.—Dr. T. Halsted Myers, of New York, read a paper with this title, and described a number of cases, chiefly in adults, in which traumatism was followed by the symptoms or deformity of Pott's disease, yet the subsequent history disproved this diagnosis. One case was that of a lad of eighteen years, who developed an abscess in the lumbar region, which opened and discharged bony spicula. After two months a small kyphos was discovered, and a spinal assistant was used to support the vertebral column. After three years a large sequestrum was discharged and the abscess closed. Dr. Myers said that when the vertebræ were fractured without injuring the cord to any extent there would not be much tenderness or local weakness, but gradually the weight of the body increased the kyphosis or lordosis, and the clinical picture came to resemble Pott's disease quite closely. It was not right, however, as was the case with the young man whose history had just been alluded to, that the life insurance companies should refuse such risks on any hard-and-fast rules, for there was much reason to doubt the existence of a tuberculous process. The special object of the paper was to direct attention to the fact that there were certain cases of traumatism of the spine, with a short and uneventful history, in which it seemed justifiable to exclude tuberculosis.

Dr. R. H. Savre, of New York, said that he could not very well agree with the author, that all cases of bone injury which terminated in recovery in a reasonable time were non-tuberculous. It was quite common to find at autopsies evidences of healed tuberculous processes, in cases in which the existence of this disease had not previously been suspected.

Hallux Valgus Extremis.—Dr. A. J. Stelle, of St. Louis, exhibited photographs of a case showing an extreme degree of hallux valgus. The toe was adducted to a right angle with the first metatarsal bone,

and the phalangeal base was displaced so as to articulate with the outer side of the metatarsal bone. The metatarso-phalangeal articulation was exposed by a longitudinal incision over the inner and upper aspect, and the base of the proximal phalanx was divided with forceps and removed. After the division of the extensor tendon the toe was readily brought into line, and was then maintained in proper position by the application of a plaster-of-Paris dressing. Dr. Steele said it was usually advised that the head of the metatarsal bone should be removed, but he had purposely avoided doing this in the present instance, since it was one of the points of the tripod upon which the foot rested, and he could not but think that its removal must impair the sustaining and propulsive power of the foot.

Dr. F. S. Coolidge, of Chicago, said that once after excision of the head of the metatarsal bone, and twice after partial excision of the head of this bone, he had noted that convalescence had been exceptionally tedious, and the pain had lingered for four or five months. In all of his cases the proximal end of the phalanx had been allowed to remain.

Dr. J. E. Goldthwait, of Boston, said that, although in his operative cases he had made it a rule to remove the head of the metatarsal bone, he had not observed any unpleasant after-effects and the patients had usually been able to walk around after two weeks.

Dr. Ansel G. Cook, of Hartford, said that he had operated upon three cases similar to the one reported by Dr. Steele, and in all of them, although the phalanx was normal, the head of the metatarsal bone was so extensively diseased as to require removal.

Dr. W. R. Townsend, of New York, said that, although theoretically scars should not be tender, it was a fact that, unless the scar was so placed as to be protected from pressure, it was likely to prove a source of much discomfort.

Dr. R. H. Sayre said that it had been his custom in these cases to remove some of the bone, even when the disease was not extensive, on the supposition that there was an overgrowth of the head of the metatarsal pone. However, the recent study of some skiagraphs indicated that the prominence of bone was not the result of hypertrophy, but of a dislocation of the phalanx, with marked separation of the first and second metatarsal bones and stretching of the transverse ligament. He now thought that division of the metatarso-phalangeal ligament would answer the same purpose as excision of the head of the bone.

Dr. Goldthwait remarked that he had done a number of operations along the lines suggested by Dr. Sayre, but convalescence had been slower—not less than six weeks—and the ultimate result, as regarded joint motion, much less satisfactory.

The Boot as an Orthopædic Appliance.—Dr. H. P. H. Galloway, of Toronto, present by invitation, exhibited a number of different styles of shoes which he had found of service in his orthopædic practice. In making a flatfoot shoe, he advised that the sole should be made to project, in addition to being made thicker on one side. As compared with an ordinary shoe, it should have a straighter inner border, greater width of sole, and a flatter sole. A clubfoot shoe, the invention of Dr. B. E. McKenzie, of Toronto, was shown. The last for this shoe was so made that the front part was bent outward at a point corresponding to the medio-tarsal joint. The heel counter was very firm, and an additional stiff bracing of leather, at a point corresponding to the first metatarso-phalangeal articulation, furnished the necessary counterpressure. In his opinion, a properly constructed cork-sole shoe should possess the following features, viz.: (1) The inside line should be nearly straight; (2) it should hold the foot in an abducted position; (3) there should be plenty of width across the metatarso-phalangeal articulation; (4) the sole of the boot should be as wide as the sole of the foot; (5) the sole should not be convex from side to side, but flat; and (6) the heel should be both broad and long.

Observations on Morton's Painful Affection of the Foot.—Dr. Royal Whitman, of New York, presented a paper with this title (see p. 189).

Further Studies upon the Arch of the Foot in Infancy and Childhood.—Dr. John Dane, of Boston, said that, as a result of the study of wet tracings of the infant's foot, he had published in 1892 the statement that the arch of the foot seemed to be present at birth, broke down again as the child began to walk, and was again found to be well built up at the age of three or four years. A recent study of this subject, made by means of measurements and hardened sections of the foot, had shown his first observations to be erroneous, chiefly owing to a pad of fat in the infant's foot giving, in wet tracings, a wrong impression of the condition of the arch. In his more recent work, the measurements were taken from (1) over the metatarso-phalangeal joint of the great toe, (2) over the tuberosity of the scaphoid, and (3) over the bearing-surface of the tuberosity of the os calcis. One hundred of these measurements of the arch showed the average to be 1.5 cm. for a child of a year, 1.51 cm. for a child of two years, and 2.73 cm. for a child between three and four years old, while for an adult it was 2.7 cm. A study of the frozen sections showed the space filled up in the infant with a pad of fat, and the arch of the foot to be perfectly formed at birth in the vast majority of cases.

Dr. Myers remarked that in a number of women wearing badly shaped shoes and having the arch of the foot badly flattened he had succeeded in giving relief by attending to the condition of the tendo Achillis and by compressing the metatarsal bones, without making the patients wear any special kind of shoe.

Dr. R. H. Sayre said that he had met with one case of metatarsalgia in which the pain had been immediately relieved by riding a bicycle and pressing the pedal up into the arch of the foot. By gouging out a place in the sole of the shoe for the heads of the metatarsal bones to rest, he had relieved the patient.

Dr. Samuel Ketch, of New York, said that in a young woman having an obstinate form of metatarsalgia, absolute relief had been afforded by the usual internal remedies for gout. She had a decidedly gouty family history.

Dr. L. A. Weigel, of Rochester, said that the mechanical support of the arch and attention to the kind of shoe worn had not proved very successful treatment in his hands. He had long ago expressed the opinion that many of these cases would not yield without appropriate medication for the underlying constitutional condition. As regarded the question of etiology, it should be noted that skiagraphs failed to disclose any such condition as had been described by Morton.

Dr. Goldthwait said that he would explain the greater frequency of anterior metatarsalgia in women by the fact that men wear wider boots, which allow the bones to rest more on the ground. Skiagraphs from these cases indicated that, in many instances, the paroxysmal pain was not the result of the crowding together of the metatarsal bones, but of the crowding of the first phalanx of the last toe against the head of the fourth metatarsal bone.

Dr. G. G. Davis, of Philadelphia, said that the simple device of wrapping adhesive plaster around the fourth toe he had found extremely effective in relieving Morton's painful affection.

Tuberculosis of Bones and Joints.—Dr. Edward H. Nichols, of Boston, delivered an address on this

subject at the evening session, held in the Harvard Medical School. It was freely illustrated with lantern slides. The diagnosis of tuberculous disease of these structures, he said, was based (1) on the more or less constant presence of the tubercle bacillus in the diseased tissue; (2) on the occurrence of the essential tuberculous structure in the diseased bones and joints, *i.e.*, the miliary tubercle; (3) on the production of general tuberculosis in susceptible animals by inoculation with the diseased tissue; (4) on the production of a similar joint or bone disease in animals by injuring their joints after having inoculated them with some of the diseased tissue or with pure cultures of tubercle bacilli; and (5) on the occurrence of general tuberculosis as a manifestation secondary to the primary focus in the diseased joint. Injuries of moderate severity favored the occurrence of tuberculous disease in bones and joints. In a very large proportion of the cases the tuberculous disease of the bones or joints was secondary to a tuberculous focus in the bronchial or mesenteric lymph nodes. The process almost invariably began in the epiphysis of the long bones, but in the "short long" bones the process frequently commenced in the shaft and spread rapidly to the adjacent bone. After an exhaustive study of one hundred and twenty cases of joint disease, Dr. Nichols said he was free to confess that he had not met with a single instance of primary synovitis. In spinal tuberculosis the presence of abscess was often overlooked during life and was first noted at autopsy. In twenty cases of excision of the hip-joint that he had examined very thoroughly, in more than half the disease was found to have begun in the acetabulum.

Dr. J. Collins Warren, of Harvard University, called attention to the extensiveness of the process in tuberculosis of bones and joints and its rare occurrence primarily in the synovial membrane, because, as he said, he regretted to see the tendency of late to believe that the disease often originated in the synovial membrane, and that consequently it was wise to resort to such partial operations as erosion of a joint or excision of the synovial membrane. The old operation of excision of the whole joint had a more sound pathological basis, and would be found to give better results in practice. On this occasion, Dr. Warren said, he desired to announce that a lady of Boston had recently left, by bequest, sufficient funds to provide for systematic and advanced scientific research into the treatment of such diseases as had hitherto proved to be incurable.

Dr. William T. Councilman, of Harvard University, then spoke of the great debt which pathology owed to the surgeon, and particularly of the far-reaching influence of that great light of both the pathological and surgical worlds—John Hunter.

Drs. R. H. Sayre, V. P. Gibney, and E. H. Bradford made suitable responses on behalf of the association.

Second Day—Wednesday, May 18th.

Proposed Apparatus for Preventing the Shortening in the Sitting Position Caused by Pott's Disease.—Dr. A. B. Judson, of New York, suggested that the appearance of patients suffering from Pott's disease might be greatly improved by having them wear under the clothing an apparatus constructed so as to collapse as the patient rose, and come into play automatically as he sat down. This apparatus would have its bearings on the ischiatic tuberosity and posterior surface of the femur, and would in this way add materially to the height of the person while in the sitting-position.

Establishment of an Orthopædic Appliance Shop.—Dr. Lemuel F. Woodward, of Worcester, read a communication embodying his personal experience in this direction, in both hospital and private practice. Except in large cities, he had found the best plan to be letting out the work by contract to a mechanic and a harness-maker, the latter attending to the covering and padding of the apparatus.

Forcible Correction of Spinal Deformities, by Stages, under an Anæsthetic.—Dr. V. P. Gibney, of New York, reported in this paper five cases which he had subjected to this method of treatment. He had been particularly astonished at the almost total absence of reaction after operation, the chief difficulty in the after-treatment being the keeping of the children in bed. Many of the patients could be hyperextended without the use of an anæsthetic, and in time an almost complete recession of the deformity could be secured in this way. The old idea, that one must endeavor to secure ankylosis as speedily as possible, seemed in the light of these recent experiences to need considerable revision, and certainly the latter offered a most cogent argument in favor of early and exact diagnosis.

Immediate Reduction of the Deformity of Pott's Disease Both with and without Ether.—Dr. J. E. Goldthwait, of Boston, presented a report embodying his experience in this new field. He said that he had soon been impressed with the facility with which the deformity could be corrected and the difficulty of maintaining what had been gained. He had simplified the treatment by using his rectangular iron frame in the application of the plaster-of-Paris jacket. The person lay on cross-straps with the head and shoulders entirely unsupported, thus making traction on the vertebræ. The frame was provided with a windlass for making additional traction, but it had seldom been necessary to use it. He had employed the treatment even in out-patient practice. He had operated upon only one case with abscess, but this one had done well. If the correction could be effected without force, he thought it preferable frequently to change the jackets, thus gaining a little at each dressing. When the disease was advanced, it could hardly be expected, from the knowledge of its pathology, that the gap would be filled in with bone, and consequently one must look for a considerable return of the deformity.

Forcible Straightening of Spinal Curvatures under Complete Anæsthesia, with a Report of Cases.—Dr. John Ridlon, of Chicago, presented in this paper his more recent experience with this method. He said that his first operation of this kind was done in June, 1897, and that since that time he had operated in sixteen cases of spondylitis, in seven cases of scoliosis, and in one case of rachitic curvature. Four cases had demonstrable abscesses, one case had an old sinus, and one paraplegia. There were no complications in these cases following the treatment—indeed, the paraplegia was positively benefited. In spite of the free use of felt padding and every precaution to prevent pressure sores, these had been of frequent occurrence. Although he had allowed only two of these patients to walk around, yet the deformity had returned to some extent in all of the cases on the removal of the jacket and traction. The risk involved in this new method of treatment seemed to him to be only that of general tuberculosis or tuberculous meningitis, just as there was after forcible straightening of tuberculous joints. This risk he estimated at ten per cent. He thought the period of treatment would be actually lengthened by this method of forcible correction.

Forcible Correction of Deformities in Pott's Disease.—Dr. F. E. Peckam said that this new treatment was naturally of the greatest service in the early stages of deformity, and that it was the treatment *par excellence* for paraplegia. In one case, in which he had attempted too much at the first operation, there was a severe and dangerous degree of shock for two or three days afterward.

Dr. Henry Ling Taylor, of New York, said that, while the extravagant claims made for this operation had not been realized, on the other hand the fears of some regarding the great danger of the treatment had been proved to be groundless. The result would probably be the adoption of a method of gradual reduction, together with better support for the diseased spine.

Dr. Newton M. Shaffer, of New York, thought that this forcible treatment was chiefly of interest in connection with disease of the middorsal region, for in the lumbar region the disease could ordinarily be treated successfully without surgical interference. A good deal of the apparent increase in height was the result of a modification of the compensatory curves, and not of a decided change in the bone itself.

Dr. R. H. Sayre thought another danger associated with the forcible correction of these deformities was to be found in the possible rupture of an abscess into the lung or of the aorta. He seriously doubted the wisdom of using much force in the effort to reduce the deformity.

Dr. C. C. Foster, of Cambridge, said that the spine could not be expected to throw out callus until the subsidence of the active tuberculous process, yet he thought a straight bone would unite just as well as a crooked one.

Dr. Judson was of the opinion that the revival of this old treatment would prove salutary by inducing surgeons to apply mechanical force properly and continuously.

Dr. A. M. Phelps, of New York, announced his intention of trying the treatment in fifty cases, and then awaiting the ultimate results. He thought that relapse would take place in all but the few cases in which the treatment was undertaken very early, and before a large kyphos had formed. The gap in the vertebral column would not heal by the deposit of bone, because fibrous tissue would grow over the ends of the bone. For this reason he was now wiring the spinal processes together, by drilling a hole through the upper vertebræ and weaving it in and out until the entire kyphos was firmly fastened together.

Congenital Dislocation of the Shoulder: Etiology and Pathology, and an Operation for its Relief.—Dr. A. M. Phelps presented this paper. He stated his belief that the origin of this condition could be traced to an injury received *in utero* or at the time of birth, and this was based on the finding of evidences of fracture in all of the cases upon which he had operated. The paralysis was considered to be purely accidental. He recommended exposing the head of the humerus by an incision along the posterior border of the deltoid muscle and dividing the capsule. The head of the bone should be cut away down to the epiphyseal line and rounded off, and then should be slipped back into the glenoid cavity. The new articulation which had formed should be removed with a gouge, and, the redundant portion of the capsule having been cut away, the remainder of the latter was sutured with catgut. To secure the very best functional result it was better to dress the arm in an elevated position.

Dr. Weigel said that as Dr. Phelps destroyed a portion of the humerus there seemed to be risk of bony ankylosis or of a flail-joint. He could not agree with him that the majority of cases that had heretofore been regarded as paralytic were really examples of this form of dislocation.

Dr. Charles L. Scudder, of Boston, said he had met with several cases of what seemed to be true congenital dislocation of the shoulder, there being a distinct difference in the length of the clavicle and in the size of all the bones of the upper extremity on the two sides. This should serve to distinguish congenital dislocation from a simple subluxation due to paralysis.

Dr. H. L. Taylor remarked that among the many cases of obstetrical paralysis at the Hospital for Ruptured and Crippled not a single case of congenital dislocation had yet been discovered.

Caries of the Spine in Adults.—Dr. E. G. Brackett, of Boston, read this paper. He stated that very few cases occurred after the age of forty years, but quite a number between thirty-five and forty. In the adult cases that had come under his observation, the disease had usually been in the lower dorsal or upper lumbar region, and traumatism assumed a much more important rôle than in early life. Thus, in three or four of his twenty cases the disease developed after a distinct strain or injury. Nineteen of the patients complained at a very early stage of a distinct pain in the lumbar muscles, just above the attachment of the erector spinæ muscles, and the symptom of stooping was often absent or but poorly marked. The early symptoms extended over periods varying from two months to two years, and were characterized by more or less distinct remissions.

Dr. Shaffer said that he had seen a large number of cases of caries of the spine in persons between the ages of thirty and sixty years. They had been for the most part traumatic in origin, and the invasion less insidious than in children.

Dr. Ridlon remarked that he had seen many more adult cases in recent years than formerly, when in New York, and he had also been surprised at the better progress made by the adults.

Bivalve Plastic Splint for Pott's Disease.—Dr. Henry Ling Taylor, of New York, read a short description of this apparatus, urging that the great principle of antero-posterior leverage should be carried out just as much in the use of plaster jackets as with steel supports. In the splint described, the ordinary jacket, made strong in front and solid at the edges, was provided with strips of felting on either side of the spinal processes and across the inside of the front, top, and bottom. While still fresh, the jacket was cut in the axillary line by two straight incisions, into an anterior and a posterior half. The breadth of these was somewhat diminished by the paring away of the sides. The bivalve splint was then trimmed, and provided with at least four straps and buckles on each side, or one side was fastened by a leather hinge. The head rest, when needed, should consist of a chin piece supported by one or two bent steel bars, which were incorporated in the anterior part of the splint. The advantages claimed were cleanliness, avoidance of excoriations, adjustability, and precision.

Some Experiments with the Celluloid Bandage.—Dr. Augustus Thorndike, of Boston, described two methods of making jackets out of celluloid. One consisted in painting on gauze bandages on a cast a varnish made by dissolving celluloid in acetone. The trouble with this plan was that many coats were required, and each coat shrank as it dried. He had found the second method very much better. Strips of thin celluloid, three or four inches wide and three yards long, were loosely rolled up like a bandage, and were then exposed to the vapor of acetone in a closed jar until soft. They were kept in these jars, and were applied to the cast or limb like ordinary roller bandages. They hardened in about twenty minutes, and a glossy finish might be given the jacket by a final coat of acetone or of acetone-celluloid paste. This method would be found useful, particularly in making splints and jackets for children, as the material was not injured by wetting with perspiration or urine.

Simple Water Pad for the Prevention of Bedsores.—Dr. Ansel G. Cook described under this head a simple expedient. It consisted, he said, simply

in improvising a water pad or bed out of four or more ice bags, which were laid side by side between two cloths and held in place with a few stitches.

Lantern-Slide Demonstration of Instantaneous Photographs of the Gait of Children in Certain Forms of Paralysis.—Dr. W. N. Bullard, of Boston, described, with the aid of some lantern views, the work done by Dr. G. W. Fitz and himself in photographing the gait of children. Double rotating shutters were employed in making the exposures. These shutters were rotated in opposite directions by means of clockwork, and gave an exposure of one-fiftieth of a second and an interval of one-fifth of a second between the exposures. In front of these rotating shutters was an ordinary pneumatic shutter. The floor and background were a dead black. When the rotating shutters were set in motion, the child was told to run across the room, and when it arrived at the desired point the pneumatic shutter was opened, and was kept open until the child had reached the farther limit of the field. To make it easier to study these photographs, white circles were marked on the knees and hips and white lines on the legs and feet of the children. The more distant leg was distinguished from the other by making its lines dotted.

Some Observations on Tuberculous Joint Disease in Colorado.—Dr. George B. Packard, of Denver, read a paper with this title. He stated that, although a large proportion of the adult people of Colorado were tuberculous, tuberculous joint disease was not so frequently observed in their offspring as in children in the East. Nevertheless, slight traumatism would often arouse the tuberculous process to activity among the numerous adults in whom the disease had been arrested. These observations were explained by the favorable influence of climate and sunshine, which made it possible for persons to spend the greater part of their time in the open air.

Dr. Shaffer remarked that these observations were an additional argument in favor of country branches for orthopædic hospitals.

New Traction Apparatus for the Treatment of Clubfoot.—Dr. Newton M. Shaffer exhibited a new apparatus of this kind, the distinguishing feature of which was the placing of the centre of motion below the foot.

Anterior Achilles Bursa Associated with Exostosis a Possible Factor in Etiology.—Dr. C. F. Painter, of Boston, read a paper with this title, in which he reported eight cases, all in adults. He said that on either side of the tendon was a tender swelling, and that the affected area was hyperæmic. In the two cases operated upon, there was profuse capillary hemorrhage, suggesting the venous stasis of inflammation. The cause seemed to be a constitutional one, and the disease was essentially chronic. In the acute stage, the treatment should be rest, heat, and bandaging.

Congenital Dislocation of the Hip-Joint.—Dr. E. H. Bradford, of Boston, read this paper. He stated that by exploratory incisions it had been determined that the relapses had been due to the falling in of the capsule, or by the cotyloid ring being too small for the neck. The bloodless method must always be uncertain. As with the cutting-operation, there was always a certain risk of infection, because the wound was very large and the drainage imperfect. The wound should be made as small as possible, and every precaution taken against infection.

Dr. Whitman expressed doubt regarding the obstacles to reduction being those mentioned by Dr. Bradford. Formerly he could not get the consent of the parents to the cutting-operation in little children; now, there was no difficulty in getting permission to operate by the bloodless method in infants of fifteen months. For this reason he was in favor of the bloodless method, if for no other.

Dr. Gibney said that he was disposed to feel as Dr. Whitman did about the cutting-operation. It was a great advantage to be able to treat these cases early.

Dr. Shaffer remarked that if the results of all the cutting-operations for congenital dislocation of the hip were tabulated and published, he believed it would effectually put a stop to that method of treatment.

Third Day—Thursday, May 19th.

Operation for the Correction of Web Fingers.—Dr. G. G. Davis, of Philadelphia, described with the aid of diagrams a method of making the flaps, which he considered an improvement on those usually employed.

Dr. Gibney said that, in his hands, the most satisfactory operation had been that in which an incision was made along the dorsal and palmar aspects of the adjoining finger, and the flap brought around and united.

Dr. Goldthwaite said that the formation of cicatrices could be entirely obviated by cutting a sufficient flap from any convenient place, and then covering the raw surface with Thiersch skin grafts.

Adenoids as a Causal Factor in Deformity.—Dr. F. S. Coolidge, of Chicago, in this paper discussed this subject, chiefly from the standpoint of prevention, taking the position that adenoids were probably the source of tuberculous infection in some cases of joint disease.

Dr. H. L. Taylor spoke of the development of acute torticollis by absorption of poison by the throat.

Dr. Shaffer referred to a case of petit mal, in which the seizures had been very favorably influenced by the removal of adenoids.

Growth in Spondylitics.—Dr. Henry Ling Taylor presented this paper. He said that the degree of retardation in these persons depended, in a given individual, on the age of invasion, the location, the amount, the severity, and the duration of the disease, as well as on the hygienic and surgical management of the case. In the average case, developing early, growth was much retarded up to the fourteenth year, from one and one-fourth to one and one-half inches being a fair rate, instead of the normal rate of two inches or more. A growth of one and one-half to two inches for some time was an indication that the case was progressing very favorably; on the other hand, if the growth was very slow, or was at a standstill, the opposite was true. Puberty and general physical development were also retarded. If the disease ceased to be active, there might be an acceleration of growth as late as the sixteenth or eighteenth year, and it was possible for such individuals to grow considerably, even after the age of twenty. Dr. Taylor suggested that, as the rate of growth gave such valuable information to the orthopædic surgeon, it should be the rule to take measurements of the standing and sitting heights of spondylitics two or four times each year.

Venereal Arthropathies.—Dr. Stewart L. McCurdy, of Pittsburg, in this paper, gave an extensive review of the literature, from which he concluded that fully seventy-five per cent. of the observed cases gave a history of either acute or chronic gonorrhœa. He also claimed that fifty per cent. of all cases of epiphysitis were syphilitic. For these reasons he was in favor of giving iodide of potassium in every case of hip or spinal disease in which there was the least suspicion of syphilis. According to his experience, the most satisfactory treatment of gonorrhœal synovitis was early aspiration and frequent injections of iodoform emulsion.

Dr. Ridlon took the ground that syphilitic joint disease was not at all uncommon, and cited certain cases to show the evidence of strong syphilitic taint and the very prompt improvement following a resort to antisyphilitic treatment. However, most of the others taking part in this discussion were opposed to his view and objected to having patients suffering from joint disease subjected to a course of mercurials and iodide without a more substantial basis for such medication.

Operation for Ununited Fractures of the Neck of the Femur.—Dr. Arthur J. Gillette, of St. Paul, read this paper, and by means of colored anatomical plates illustrated the method of operating. He reported three cases successfully treated by the method advocated. The operation, he said, was simple, and was performed as follows: A horseshoe-shaped incision was made over the hip, extending from about the anterior superior iliac spine to below the trochanter major, and back to a line opposite the anterior superior spine, about the centre of the gluteus maximus. A chain saw was then passed between the posterior edge of the tensor vaginæ femoris and the anterior border of the gluteus medius, and was brought out from behind the muscles. The trochanter major was then sawed off. It was next thrown back with its muscular attachments, exposing thoroughly the capsule of the hip-joint, on division of which the fracture was laid bare. The fractured surfaces were next freshened, and a bone-peg was driven from the surface where the trochanter major was removed through the neck of the femur. The trochanter major was then secured in its normal position by a bone peg.

Elongation of the Ligamentum Patellæ as a Factor in the Production of Hey's Internal Derangement of the Knee-Joint.—Dr. N. M. Shaffer read this paper. He stated that there could be an elongation of the patellar ligament without subluxation of the semilunar cartilage, provided there was not much lateral mobility. The object of his treatment had been to allow only of antero-posterior motion.

Voluntary Lateral Dislocation of the Knee in Infants.—Dr. Augustus Thorndike, of Boston, reported in this paper two cases in infants of about a year old, in which the ligament admitted of considerable lateral and rotary motion when the knee was straight. When it was flexed from twenty to forty-five degrees a voluntary dislocation could be produced, and it could be reduced by flexing to a right angle or by extending the knee. In one of the cases a good result was obtained by the use of a simple hinge splint.

Report of a Case of Spontaneous Dislocation of the Hip during Typhoid Fever.—Dr. L. A. Weigel, of Rochester, reported a case of this kind in a girl of eight years. It occurred in the sixth week of the typhoid fever. It was reduced under anæsthesia, but recurred in ten days. It having been again reduced, the joint remained in position permanently, or at least was in position when last seen, which was a few weeks afterward.

Bed Position as an Etiological Factor in Spinal Curvature.—Dr. G. W. Fitz, of Boston, made a few remarks on this subject in connection with a lantern exhibition of a series of photographs projected on the screen. According to his observations, sleeping on the same side habitually tended to fix a curve of the spine by favoring the growth of the bone and ligaments on one side, and retarding the growth on the other. The common habit of curling up in bed tended to exaggerate the effect of lateral bed position.

Officers Elected.—Dr. W. R. Townsend, of New York, was elected president, and Dr. John Ridlon, of Chicago, secretary of the association.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE EXODUS TO EDINBURGH—PROFESSOR MARTIN'S ADDRESS TO THE GYNÆCOLOGICAL SOCIETY—PREVENTION OF TUBERCULOSIS—THE VACCINATION BILL—OTHER BILLS—THE PRINCE OF WALES.

London, July 29, 1898.

For the nonce the centre of medical attraction has shifted to Edinburgh, where a number of our brethren are enjoying the far-famed hospitality of the northern capital. It is common enough to hear it said that every one has gone to Scotland, but a considerable allowance must be made for the *modus loquendi*. There is no fear of any one being unable to find a doctor in London, for after all departures there are five thousand of us left to look after the invalids. Nor are we left without our share of pleasant or instructive meetings. On Saturday, for instance, the Gynæcological Society provided us with a sensation. Professor Martin, of Berlin, had accepted an invitation to deliver an address before the society, and, taking London on his way to Edinburgh, discoursed on "The Development of Ovariotomy" in a manner that delighted a distinguished audience, among whom were the medical chiefs of the army and navy, Professors Gardner, Jacobs, Young, Lapthorne Smith, Landau, Sanger, Mangiagalli, and a number of others who took the opportunity of attending this special meeting of the society while *en route* for the north. When a renowned operator with enormous experience addresses an audience specially skilled in his subject, he is naturally listened to with profound attention. When he quietly relates the difficulties he has met with and the methods he has adopted to overcome them, of course those who have encountered them, too, though with less experience, are deeply interested. So it was with Professor Martin, who modestly referred to his success and laid before the society the results of his experience. At the outset he reviewed the historical development of ovariotomy from the time of McDowell, and referred to Clay, Atlee, Peasley, Baker Brown, Thomas Keith, Spencer Wells, Stilling, Koeberlé, Hegar, Battey, Tait, and so on. The influence of antisepticism and of bacteriology was noticed and the professor then passed on to discuss the questions which at the present time most interest ovariotomists. He expressed great pleasure at reading Clement Cleveland's paper in the Medical Record of April last. Then he considered the conditions most suitable for vaginal colpotomy and the difficulties which may be met with, and added: "I always bear these difficulties in mind and I have not yet had a single case out of over seven hundred in which I had to abandon the vaginal operation and finish the operation by the abdominal method."

In speaking of vaginal ovariotomy Dr. Martin said he had lost only two cases out of one hundred and thirty-one, or 1.5 per cent. In Wells' early time the mortality of abdominal operations was twenty per cent. To-day it is only from two to five, and many operators can report a long run of recoveries in more or less complicated cases. "I do not deny," said Professor Martin, "that in those cases selected for vaginal ovariotomy there is often less complication by way of adhesions, metastasis, and so on, so that statistics of the two methods must be compared with great reserve. We all agree that statistics are often misleading, and we need to exercise great care not to be wrongly impressed by them." Professor Martin concluded by thanking the society for the honor done

him by the invitation, which he regarded as offered equally to all German gynæcologists.

The president, Dr. Macnaughton Jones, referred to the many important points which had been dealt with by this master of their art, and proposed a hearty vote of thanks to him as an honorary fellow of the society for his able address. This was seconded by Dr. Routh, whose recollection enabled him to speak from personal knowledge of the work of Baker Brown and Spencer Wells. Dr. Bantock supported the motion, which was carried with applause and briefly responded to by Dr. Martin.

I lately reported to you the proposal to form an association for the prevention of tuberculosis. The society has now been established and a circular issued, signed by Sir S. Wilks, Sir W. MacCormack, and Sir W. Broadbent. Mr. Morris is treasurer and Dr. St. Clair Thomson secretary. The subscription is to be 5*s.* per annum, or £5 5*s.* for a life membership. The objects are stated to be the dissemination of information, arousing public feeling and establishing sanatoria.

The government has not heard the last of its weak concession to the antivaccinationists. Some of its regular supporters are so discontented that they purpose to reject the bill altogether at its last stage. It will be no loss if it is rejected, now it is emasculated. Nearly all the leading journals condemn the concession, and Sir G. Stewart's Edinburgh address is having considerable influence.

As an exception the *Saturday Review*, often dubbed *Saturday Sneerer*, comes out with a fling at doctors, saying the belief in them is obviously diminishing, and coarsely suggesting they find money in it, adding that they are taking the place of the parsons, "whose business was also confined to prophylactic measures." The *Sneerer's* wit seems deteriorating.

There is to be a Saturday's sitting of the house tomorrow, in order to deal with the bill. It will then be seen whether it can be passed or will be dropped.

The Prince of Wales is as well as could be expected in the short time that has elapsed since his injury.

Prof. William Osler has received an honorary degree from the University of Aberdeen.

The pharmacy amendment act has received the royal assent.

The habitual-inebriates bill is making steady progress.

THE PHYSICAL EXAMINATION OF RECRUITS.

To the Editor of the Medical Record.

Sir: In the number of July 23d of the Medical Record attention is called to the general order recently issued from the adjutant-general's office of the war department, requiring closer attention to the physical condition of men examined and accepted for service. This order has caused some surprise, because it was supposed that the examinations were already extremely severe. As bearing upon this question, I should like to submit a few figures from the experience of the Washington Life Insurance Company, of this city. This company, some two months ago, began to receive applications for life insurance from members of the volunteer and regular army service. During this period, 285 enlisted men have been examined by the company's medical examiners. Of the 285, 34, or about 12 per cent., were rejected or deferred for various causes. The principal causes for rejection were as follows: Pulmonary disease, 7; albumin in the urine, 7; heart disease, 5; frail physique, 2; intemperate habits, 3; catarrh of the ear, 1. The other causes for rejection of the applicants do not bear upon the personal condition of the men, but had reference to history of recent illness or to unfavorable family record—questions which do not, perhaps, concern the army administration. At least twenty-five, however, of the individuals rejected were, in my opinion, unfit for service. I have been informed that no analysis of the urine is made by the army examiners. It will be seen from the above figures that this is a grave omission. Most of the examinations in the above cases were made at Jacksonville, where the company has a most capable examiner. The soldiers belong to regiments from all parts of the country, including Illinois, Wisconsin, Virginia, New Jersey, North and South Carolina, New York, South Dakota, Florida, Missouri, Georgia, and California. One of the individuals who was rejected because of "frail physique" was five feet eleven inches in height, weighed one hundred and thirty-five pounds, and had a chest measurement of only thirty inches. Such men hardly seem fit to endure the hardships of service in the field.

John W. Brannan, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 6, 1898:

	Cases.	Deaths.
Tuberculosis	100	145
Typhoid fever	29	15
Scarlet fever	71	6
Measles	102	11
Diphtheria	118	12
Laryngeal diphtheria (croup)	2	2
Cerebro-spinal meningitis	0	11
Chicken-pox	5	

Health Reports.—The following statistics concerning small-pox, yellow fever, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending August 6, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Alabama, Hurricane Bayou	July 28th	1	
Mobile	July 30th	1	
Colorado, Boulder County	July 26th	1

ON CONGENITAL HYPERTROPHIC STENOSIS OF THE PYLORUS IN INFANTS.*

BY S. J. MELTZER, M.D.,

NEW YORK.

(From the Department of Pathology, College of Physicians and Surgeons Columbia University, New York.)

IN the medical literature of this country there are on record, as far as I can see, only four cases of congenital stenosis of the pylorus in children, and two of these are described by Ashby,[1] of Manchester, England. However, there are sufficient reasons to believe that this affection is not so rare as it would seem to be, judging by this scarcity of record. In the European medical literature of the last few years we see a constant growth in the reports of these cases. In 1896 Finkelstein[2] collected eleven cases, and in 1897 John Thomson[3] gives a *resumé* of sixteen, not including two cases of Henschel,[4] and now four new cases are to be added—one by Schwyzer,[5] two by Ashby,[1] and one by Rolleston and Haynes.[6] Furthermore, an analysis of these cases shows that they can hardly be taken as a fair representation of the actual occurrence of this form of disease. The first case on record was described by Williamson,[7] in 1841, and the second was reported by Davoski,[8] 1842. Then a period of forty-six years elapsed with no reference to this affection, until in 1888 Hirschsprung,[9] of Copenhagen, inaugurated the present new series of records. Again, in this new series we find that two cases are reported by Hirschsprung, four cases by Finkelstein and by Gran[10] from Heubner's clinic, three cases by Thomson, two by Schwyzer, and two by Ashby—each group of cases being observed by the respective writers only within a short period. This shows that if the attention of an observer was once called to the existence of this affection, he did not fail soon to discover another case. A few years previous to the publication of Hirschsprung, the subject of congenital stenosis of the pylorus had been treated by Landerer[11] and by R. Maier.[12] The latter has published thirty-one cases (including ten of Landerer) of stenosis of the pylorus, which were collected in the autopsy room within the course of only a few years. They considered these cases as congenital, on the ground that there were no signs of a pathological state (catarrh, ulcer, etc.) which could have caused the hypertrophy and stenosis of the pylorus. However, as the youngest of these patients in which the stenosis was observed was twelve, and the oldest eighty years, the assumption of these authors that the stenosis was not acquired was not beyond doubt; and as the reports of Williamson and Davoski were forgotten long ago, it then remained still an open question whether congenital stenosis and hypertrophy really occur. And herein lay the incentive for the report of Hirschsprung. The observation of stenosis and hypertrophy in a child only thirty days old brought the requisite proof that these conditions may indeed be congenital. Now the twenty-two cases of congenital stenosis in infants recorded in the literature have all been found at autopsies, and in only four of these cases was the correct diagnosis made *intra vitam*. But in the light of the statements of Maier and Landerer, who consider the stenosis in their cases as congenital, we must assume that some of these subjects of congenital stenosis of the pylorus not only survive infancy, but also attain sometimes even advanced age: then the expectation is justified that an early recognition and proper treatment of these cases may be instrumental in saving the lives of some of these infants. And indeed there are already four cases on record in which the proper diagnosis was made and by means of efficient treatment the children were kept alive. It is worth mentioning that three of these children were under the care of Heubner,[10] from whose clinic four autopsies of this kind were reported, and one of the cases comes from Henschel, who reported two autopsies. We may also add here that in the few cases with autopsies in which the condition was recognized during life, the respective physicians, it seems, were enabled to make a proper diagnosis by having seen previous autopsies of this kind of cases. Thus Thomson made a correct diagnosis in his third case, Schwyzer in his second, and Finkelstein after having seen the cases of Gran in Heubner's clinic.

This brief review teaches us that the cases of congenital stenosis of the pylorus are by no means very rare, and that the mere calling of attention to the existence of this disease was often instrumental in bringing out more such cases,* and in some instances it enabled the physicians to make an early diagnosis and even to save the life of the little patients. With these considerations in my mind, I ask your permission to report here and discuss in detail a case of stenosis of the pylorus in an infant of six weeks, in which I was fortunate to see my diagnosis confirmed by an autopsy *in vivo*, but I regret to be also able to demonstrate to you now the correctness of my diagnosis by a remarkable anatomical specimen.

L. K—— was a well-developed, plump baby when she was born, on December 10, 1897, from a nervous, pale, and thin mother and a healthy father. I was called to see the child three days later. She was constantly crying, except when she took the bottle, from which she drank hastily and with unusual eagerness. The mother had no nipples, and the child was fed with milk and water, one to four. She vomited occasionally immediately after drinking, the milk being yet uncurdled: the bowels were evacuated by oil and by calomel. There was blennorrhœa of the right eye. I advised that the baby be fed with smaller quantities but at regular intervals, and prescribed hydrochloric acid and aqua laurocerasi, to be given before each feeding. This had a favorable effect—the child was resting better, drank from the bottle with less haste, and retained the milk.

I was next called on January 2, 1898, about three weeks later, and was told that the medicine had been given for some time and then discontinued, the condition of the child appearing to be satisfactory. But

* Read at the annual meeting of the Association of American Physicians, Washington, D. C., May 2, 1898.

* A gentleman from Boston informed the writer that while listening to this paper he became convinced of having had a case of this kind under his observation.

meanwhile the nipples of the mother's breast were drawn out and the child was put to the breast, and soon the vomiting commenced again and was more profuse than before. When I was called at this time the baby was vomiting every time immediately after taking the breast, the milk was curdled, and the vomit smelled strongly acid; the movements of the bowels were retarded. The child was again very restless, cried constantly, had hardly any sleep, and baby and mother looked quite worn out. I stopped the mother's nursing, washed out the baby's stomach with warm saline, and gave calomel, which was retained and had a good effect. The baby now received only oatmeal water, the first day one ounce and in the following two days two ounces every hour. Before each nursing the child was given some bicarbonate of sodium and cherry-laurel water. The child now retained all that it was given, the bowels moved spontaneously, the heretofore diminished diuresis increased again, and the baby again rested better.

Meanwhile a promising wetnurse was procured, and on January 6th the child was again put to the breast. The baby took it with eagerness, drank hastily, emptied one breast in a few minutes, and soon vomited apparently all that it had swallowed. This occurred every time when the child was put to the breast. It being supposed that the eagerness and haste with which the child took the breast might be the cause of the vomiting, the milk was withdrawn by a pump and then given to the child slowly and in small quantities. I had also changed the bicarbonate of sodium to hydrochloric acid. At first the new arrangement seemed to work favorably—the child vomited but once in five or six hours, the milk came up only in small quantities, contained flocculi of small curds, and had no abnormal odor or appearance. It was now attempted to increase gradually the quantities given at one time; but within a few days the vomiting, too, gradually increased in quantity and frequency. I attempted to empty the stomach by a Nélaton catheter at a time when the child had not vomited for a few hours, and found that the quantity which was thus removed was about equal to the amount which the child had taken within the last few hours. When now I examined the abdomen, I found the empty stomach rather strikingly contracted, easily palpable like a little tumor, and lying in the middle line high up in the epigastrium. There was then no atony of the walls of the stomach; nevertheless it harbored a large quantity for hours without being able to empty it into the intestines. For the first time now it dawned upon me that I might have to deal here with a high degree of stenosis of the pylorus, and I started out therefore to establish this diagnosis by proper methods.

The following data were gradually collected within the next few days. When the stomach was filled with water under moderate pressure the entire epigastrium bulged up, and on percussion the dulness of this region terminated about one finger above the umbilicus. The bulging upper part of the abdomen contrasted sharply in appearance with the sunken lower part. When the stomach was moderately inflated with air, the contrast between the upper and the lower parts of the abdomen was still more striking and the stomach seemed then to reach the umbilicus. When the stomach was filled with water and the colon inflated with air, it was easily seen that the stomach was lying just next to the wall and the colon beneath it. When the stomach was filled with water, or during and after nursing, peristaltic waves could distinctly be seen passing over the region of the stomach from the left to the right side. While the child was quiet the lower end of the soft catheter, when pushed deeply into the stomach, could be felt bent around and running alongside the large curvature, marking in this way the lower border of the stomach (method of Boas). When there was some liquid in the stomach and air was blown through the catheter, the air which escaped from its inside opening into the surrounding liquid caused a gurgling sound; the auscultation of this sound was utilized to locate the lower end of the catheter and with it the lower border of the stomach. By these latter methods and by percussion the size of the empty stomach could be established, even when it remained permanently relaxed, which was, indeed, soon the case. The tumor-like contraction which was mentioned above was observed only twice, in the beginning of the scrutinizing examination. In the consecutive period it was found that the stomach remained relaxed even in a thoroughly empty state, and that gradually it assumed larger proportions. It was then evident that there was a serious degree of stenosis of the pylorus, which gradually brought out hypertrophy and dilatation of the stomach.

I started now to wash the stomach daily, which revealed at the same time the fact that even violent and frequent vomiting attacks never thoroughly emptied the stomach. As I had to settle now for a permanent state, I had to let the nurse give the child the breast directly, as she was unwilling to continue the feeding by the previous methods; it was nursed very frequently, but only for a few minutes at a time. The bowels were greatly retarded, but promptly responded again to a dose of calomel, which seemed to show that there was still some free communication between the stomach and the intestine. The mixture of the hydrochloric acid and the aqua laurocerasi was discontinued, as I feared especially the paralyzing effect of the latter on the contractility of the stomach. The extreme restlessness of the child, however, necessitated the resumption of the latter drug again, but very small and infrequent doses were sufficient to keep the baby in a tolerably tranquil state. For a number of days the condition was a tolerable one; the child was resting, vomited only four or five times a day, passed sufficient urine; the bowels moved once or twice a day. On the 17th, 18th, and 19th of January the stomach was not washed. It was noted by the family with satisfaction that on these days the child vomited less than before. On the 20th, however, it was found that the child had meanwhile lost a few ounces in weight, that she urinated very scantily, and was again constipated. An examination of her abdomen showed that the stomach now extended far below the umbilicus, and the peristalsis was nearly entirely absent. The stomach was emptied with a catheter, and it was found to have contained eight ounces of curdled milk mixed with tenacious mucus. A renewed attempt to wash the stomach more frequently brought no perceptible change in the now quite hopeless state.

It was then decided to attempt to help the child by means of an operation. The child was still in a tolerable state, was not emaciated, and offered a fair chance to stand an operation. This was done by Dr. Willy Meyer on the 23d of January. The child was then forty-four days old. The operation lasted about forty-five minutes; the baby stood anæsthesia fairly well (Schleich's mixture); hypodermics with stimulants were freely administered. As soon as the abdomen was opened, the very large stomach filled with air presented itself. It had already the configuration and the position of the stomach of an adult. The walls of the stomach, especially of the pyloric part, appeared to be thickened. The pylorus itself offered a striking appearance; it looked like a little tumor of the size of a large cherry, uniform in all dimensions. The intestines appeared to be totally empty. The surgeon then quickly performed gastro-enterostomy by means of a Murphy button of the smallest size he could then obtain. The baby appeared after the operation to be in a tolerable state. Hypodermics were continued; an at-

tempt at transfusion was unsuccessful, on account of the minuteness and emptiness of the infant's veins. A few hours after the operation, however, the child started vomiting small masses of a brownish-black color; this was followed by frequent tremors, which gradually developed into convulsions. The temperature rose to 103° F., and, although convulsions and fever

subsided after some time, the child gradually collapsed and died, thirty hours after the operation. The child vomited no bile and the diagnosis was correctly made before death. The button was too large for the exceedingly narrow jejunum, and not only prevented the stomach from emptying its contents into the intestines, but also caused a stagnation of the bile in the parts of the duodenum and jejunum lying between the pylorus and the place of the anastomosis with the stomach. (I may remark here that the infant never during her short life vomited bile, and also that she never vomited at any other time except immediately after drinking.)

The autopsy was restricted to the abdominal cavity. There was no trace of inflammation. All the intestines were absolutely empty; no other abnormalities presented themselves. The stomach with the part of the intestines connected with it by means of the Murphy button was removed. The stomach is of remarkable size; it measures, from the outer end of the fundus to the pylorus, eleven centimetres. The fundus is remarkably well developed; its walls are very thin, but the walls of the pyloric portion are quite thick. This portion is funnel shaped, and ends in a fine opening leading into the pylorus proper, the walls of which are considerably hypertrophied; the lumen permits the passage only of a fine probe of less than one millimetre thickness. The narrow channel, which is not straight but presents rather a broken line, was obliterated with tenacious mucus. The peculiar appearance of the thick duodenal end of the pylorus with the tenacious mucus hanging from it strikingly reminds one of the vaginal portion of the uterus protruding into the vagina. The contrast between the hypertrophied pylorus and the very thin-walled duodenum is here the more sharp, as duodenum and jejunum present acute dilatation due to the stagnation of the bile within them during the period elapsed between the operation and death.

Prof. T. M. Prudden, who kindly examined the specimen, made the following report: "On a longitudinal section of the pyloric portion of the stomach, in the line of the greater curvature and extending into the duodenum, the pylorus (hardened in formalin followed by alcohol) measures, from the tip of the gastro-duodenal valve to the point at which the pyloric portion rather abruptly merges into the general stomach wall, 3.5 cm.; the thickness of the entire wall just back of the tip of the gastro-duodenal valve is 4 mm. Passing backward toward the stomach, the wall gradually thins, until at a point 7 mm. from the tip of the valve it measures 3 mm. It then gradually thickens, maintaining for about 1 cm. an average thickness of 4 mm.; then thins abruptly, to merge into the general stomach wall. The mucous membrane is thrown into a series of longitudinal folds.

"The microscopical examination shows that the thickening is largely due to the presence of dense fibrous tissue in the submucosa and to a hyperplasia of the inner muscular layer, especially of the proximal half of the pyloric portion. The moderate thickening of the wall at the gastro-duodenal valve, which gives to this structure an undue prominence when seen from the duodenal aspect, appears to be almost wholly due to the fibrous hyperplasia in the submucosa; while at the other—the proximal end of the pyloric portion—both the inner muscular layer and the submucosa share in producing the thickening of the wall. The external muscularis presented no abnormality. The mucous membrane was not sufficiently well preserved to permit the detection of any abnormality, save a general slight encroachment between the bases

of the glands of the hyperplastic tissue in the submucosa.

"The anatomical diagnosis is, accordingly, stenosis of the pylorus, from fibrous hyperplasia of the submucosa; hyperplasia of the inner muscular layer, especially of the proximal half of the pyloric portion of the stomach."

When we recapitulate briefly the main features of the case, we see that in the first two weeks there were

no other symptoms except restlessness and extreme eagerness for drinking, with occasional vomiting. But this soon became very frequent, and continued so until a few days before death. The vomiting was always accomplished with force; it occurred soon after drinking, and at no other time; the vomit never contained bile, and did not show any fermentation or other signs of a catarrhal condition of the stomach. Until a few days before death the bowels moved tolerably well and responded promptly to calomel. A study of the dimensions and contractility of the stomach has demonstrated that, at the beginning of the fourth week when the examinations were first made, the stomach was rather unusually contracted when empty and showed lively peristalsis when full. Gradually, however, apparently a state of atony of the stomach developed; it became more and more permanently dilated, extending over the larger part of the abdomen, and no more peristalsis was seen. And just at this juncture the vomiting seemed to diminish, but with no sign of food passing into the intestine or being absorbed from the stomach. There was no defecation and but little urination, and the child commenced to lose weight.

That the extreme narrowness of the lumen and the remarkable hypertrophy of the walls of the pylorus were not acquired within the very short period of the child's life, goes without saying; there were no signs of an ulcer, an inflammation, or of anything else which could cause such a stenosis and hypertrophy. The extreme stenosis was there from the very first; it was congenital. Nevertheless, from the beginning to a few days before the end, food doubtlessly passed through this extremely narrow channel from the stomach into the intestines—at least in such a degree as to enable the body to keep up a metabolic equilibrium. There was no loss of the original weight. Then there were passages of fæcal masses from the bowels, and calomel had always shown its unmistakable effect. Surely, contents of the stomach managed to get through the pylorus with a lumen of hardly one millimetre. It is a remarkable fact, but has illustrative parallels in the autopsies reported by Landerer and Maier. The following instance (Landerer) is very instructive. In a man of forty-five years, who died of marasmus, an enormous stomach was found, in which the lumen of the pylorus measured only two millimetres in diameter, with no hypertrophy of the walls. This man suffered from his infancy from nausea, bloatedness, and other dyspeptic symptoms. The stenosis in this case was apparently congenital; nevertheless, the owner of this exquisitely narrow pylorus managed to attain the age of forty-five years.

Turning to our case again, it would seem to me that the life history of this stomach could properly be divided into three phases first, the phase of simple insufficiency; then the phase of attempted compensation: and finally, the phase of atony and permanent gastrectasy. The stomach of this newborn, when filled for the first time to its full capacity, could, in the interval before the second feeding, empty only a part of its contents through the stenosed pylorus into the intestines. When the second feeding took place, there was still present in the stomach some of the food previously taken: the organ then became overdistended. But the increased distention of the muscular walls called forth, as usual, an increased contractility of its normal muscle fibres, and herewith a greater pressure of the walls of the stomach was exercised upon the contents, which were now driven out into the intestines in a somewhat greater proportion than in the former interval. Notwithstanding this greater removal, the balance remaining in the stomach was greater now than in the foregoing interval. After a few feedings, when through the accumulation of the several balances the stomach became extremely distended and the muscular fibres were incited to their utmost contraction, the high pressure which was now exerted upon the contents of the stomach became capable of overcoming the tonic contraction of the cardia, and the entire contents or most of them were now expelled through the œsophagus. After this forcible evacuation, the stomach probably assumed its original dimensions, and the circle could commence anew. The temporary distention of the stomach was not yet gastroectasy; the stomach walls still retained their full tonus, but there already existed a state of insufficiency—the stomach was unable to empty its contents entirely into the intestines. The body was under these circumstances insufficiently nourished, and though with the increased pressure within the stomach a greater transmission of food into the intestines took place, the amount was probably incongruent with the requirements of a body in its first growth. Herein lies the cause for the greediness which the child displayed in taking the nursing-bottle; and as for the constant crying of the child, there are still several other reasons. The overloaded stomach undoubtedly gave a sense of uneasiness; then the increased contractions of the stomach might cause some pain, and perhaps also the contractions of the hypertrophic pylorus caused special pain, and especially when there was a struggle between the antagonistic contractions of the stomach and of the pylorus. In adults we know that in stenosis of the pylorus the cardialgic pain is a predominant symptom. Greediness and restlessness have been present from the very beginning in many of the reported cases of congenital stenosis of the pylorus.

The constant overdistention of the stomach causes after a longer or shorter period a more or less pronounced degree of hypertrophy of the muscular sheath of the stomach.* When this is accomplished the stomach responds even to a moderate overdistention with an unnecessarily strong contraction, capable of throwing out the entire contents through the cardiac aperture, and this the more so when after repeated attacks the aperture becomes somewhat dilated. It is my belief that the appearance on the scene of the frequent attacks of vomiting immediately after drinking, without any other catarrhal symptoms, is a sign that a compensatory hypertrophy of the muscular tissue of the stomach had already taken place. In one of the cases recorded by Hirschsprung, the author hardly credits the statement of the parents that the child appeared to be perfectly well in the first ten days of its life. This, however, is apparently rather the rule. In most of the cases on record the frequent vomiting did not set in immediately after birth, but one or more weeks later, which fact finds its explanation, as I believe, in the assumption made above, that the frequent vomiting started with the development of the compensating hypertrophy of the stomach, which, of course, did not set in until some time after birth.

The pressure which the contraction of the hypertrophied muscular walls exerts upon the contents of the stomach affects not only the cardiac aperture, but also the aperture of the pylorus and the conditions of the fundus. In the former case the effect might be a favorable one; the increased pressure might help to dilate the stenosis just as it overcomes the tonic contraction of the cardia. Its effect upon the fundus, however, is decidedly an unfavorable one. The walls of this part of the stomach are less muscular and do not take part in the hypertrophy of the rest of the organ. When now the hypertrophied pyloric portion exerts a considerable pressure upon the contents, it drives a part of them into the unresisting fundus, with the result that this part becomes gradually more and more dilated. The evacuating power of the pyloric por-

tion does not empty all the contents, but rather a considerable portion remains in the fundus; this remaining portion of the contents becomes larger and larger, the larger the fundus is. Finally, the contraction of the hypertrophied portion becomes ineffective, or, what is still worse, this portion itself loses its contractility, the muscle fibres become degenerated through overexertion, assisted perhaps by the malnutrition, and then the final state of gastroectasy is reached.

Diagnosis.—The diagnosis of the last stage, of the permanent gastroectasy, offers no difficulty. The mere inspection reveals the contrast between the bulging of the upper part and the collapsed state of the lower part. Then the percussion of the stomach filled up with air or water, the palpation of the catheter within it, and the auscultation of the gurgling sound produced by the air blown into the partly filled stomach, as described above, will sufficiently demonstrate the presence of a gastroectasy. In the second stage we might rely upon the following symptoms: the change of the area of percussion with the degree of filling of the stomach, the appearance of peristaltic waves over the region of the stomach, the palpation of the contracted stomach in an empty stage. In both these stages, but especially in the stage of the compensatory hypertrophy, the frequent vomiting immediately after drinking, the absence of vomiting at any other time, the absence of bile from the vomit, and its non-catarrhal appearance, are symptoms quite characteristic of stenosis of the pylorus.

In the first stage we shall rarely be consulted, but if we see a child which is extremely restless and drinks greedily we ought to think of the possibility of a congenital stenosis of the pylorus, and our next step ought to be to introduce a catheter into the stomach and empty it two hours after feeding. If we then find in the stomach a noteworthy balance while the amount of the feeding was normal, we know that there is an insufficiency present and have to watch the further development. The introduction of a catheter for the sake of establishing the sufficiency or insufficiency ought to be done in all the stages of this disease and in all cases in which we find frequent vomiting.

Treatment.—In treating this affection we have to remember that there are cases on record in which the patients managed to live to a comparatively advanced age with a very narrow pylorus. But we should also remember that a piece of tenacious mucus, a large coagulum sticking in the pylorus, or a slight kink in it would suffice to make such a pylorus entirely impenetrable. We must also remember that the successful passage of food through such a pylorus largely depends upon the contractility of the stomach, and that an ectatic stomach does not contract and is besides liable to produce by its weight fatal kinks of the pylorus. The treatment of the first and the second stage consists mainly in two points: the proper regulation of the feeding and the frequent emptying and washing of the stomach. With regard to feeding, it would seem to me that at least in the first stage the amount given at one time should slightly overstep the capacity of the stomach. The distention which is caused by it will bring out a better contraction of the muscular tissue, which will not only drive more food into the intestines, but may also serve to a degree as a means of gradual dilatation of the stenosed pylorus. The emptying of the stomach, however, must be done quite frequently: the washing is under these circumstances a less important matter, and the emptying alone is such an easy procedure that it could be carried out after some practice by any member of the family. In the second stage only a small amount can be given, as larger ones would immediately be rejected by the stomach, but the feeding must be carried on very often, at least hourly. In the early period of this stage it is probably sufficient to empty and wash the stomach once a day, as the frequent vomiting acts partly as a safety valve against the overcrowding of the stomach. It should not be attempted to stop the vomiting by means of narcotics or bismuth. I have used a narcotic myself, and I see in Finkelstein's statement that Heubner also used it. However, I now think that narcotics are harmful, inasmuch as they paralyze the contractility of the stomach, which is the most indispensable factor in our struggle. Bismuth might entirely obliterate the small opening of the pylorus. For the same reason I believe that cow's milk should not be employed in these cases, as it forms large coagula in the stomach. Heubner's method of washing the stomach with one-half-per-cent. solution of Carlsbad salts should be employed. It will help to keep the narrow passage of the pylorus free from mucus. The tenacious mucus which was found in my case to stick within the pylorus might have been the cause of the absolute occlusion which was observed in the two days previous to the operation. Massage of the stomach in the direction from left to right should be practised, which might assist the stomach in emptying its contents into the intestines. A bandage around the stomach might also prove to be beneficial, but it ought to have a pad fitting and filling out the epigastrium and reaching to the navel, in order to exert an efficient pressure upon the stomach, which might prevent to a degree its extreme dilatation and help it at the same time in pressing its contents into the intestine.

That the rectum should be utilized for additional nutrition and that hydropathic and other measures to improve the general condition of the little patient should be employed are self-understood and do not require any particular discussion.

In the last two stages, besides all the measures mentioned above, there comes in addition the operative treatment into consideration. In adults the operative treatment for benign strictures of the pylorus is an established procedure, and, as is well known, furnishes quite favorable results. For the class of cases we are dealing with here, Schwyzer was the first one to discuss the advisability of surgical interference. He mentions Loretta's operation and gastro-enterostomy. Loretta's operation, or the digital divulsion of the pylorus, is apparently here out of question, especially when the lumen of the pylorus measures not even one millimetre in diameter. Gastro-enterostomy, however, is at present generally employed in cases of benign strictures of the pylorus in adults, and is, naturally enough, the operation which suggests itself for the relief from hypertrophic stenosis of the pylorus in infants. And here again, where the gain of time is surely a very important point, apparently Murphy's button deserves the preference over the anastomosis by suture. The operation in my case, the first one ever performed for the relief of congenital stenosis of the pylorus in infants, was done with the Murphy button and was not a success; this, however, was due only to the inadequate size of the button, which can be avoided in the future. Indeed, Dr. W. Meyer has now had small buttons made, which will probably not block the free passage in the jejunum of even very small infants, and he is of the opinion that the button ought to be given the preference over the anastomosis by the suture—in fact, over any other method.* It seems to me, however, that there are well-founded objections to the employment of a Murphy button in infants. In the first place, it is very probable that here the button will not pass off through the very narrow,

* Soon after the operation in my case Dr. I. Adler in New York met with a similar case, and here Dr. W. Meyer made the gastro-entero-anastomosis by suture. This child died a short time after the operation, but it was, as I understand, in a very debilitated state.

exceedingly contracted jejunum, but will rather enter into the stomach and remain there. In the second place, there comes up quite a serious question as to the future effectiveness of the small communication established by the small button between the stomach and the intestines. In a case of Czerny, in which the opening made at the operation measured three centimetres, it was found at the autopsy, five months later, that the opening was reduced to only eight millimetres. This occurred in an adult in whom the solid food taken might have had a dilating tendency upon the opening. What, then, will be the fate of the opening in the stomach of an infant, with its liquid food? And it would seem to me that the growth of the stomach and the body in general would rather exercise an obliterating tendency upon the artificial opening. We must also bear in mind that the motility of the stomach is arranged to propel the food in the direction toward the pylorus and not toward the places usually selected for the artificial opening, and that the peristaltic wave, instead of assisting in pressing the food through the artificial opening, will rapidly carry it away from there. These considerations, however, not only speak against the use of the Murphy button, but also make the advisability of the employment of gastro-enterostomy in infants altogether questionable.

It seems to me, therefore, that the typical pylorectomy (Billroth) is the ideal operation for the relief of the hypertrophic stenosis of the pylorus in infants. The objections against the use of this operation in the stenosis of the pylorus in adults arose mostly from its exclusive employment in malignant cases, in which the adhesions, etc., made it quite a difficult operation. It seems that even there we are now at a turning-point in its favor (Keen). In cases of benign stenosis in infants, the removal of the hypertrophied pylorus will re-establish normal conditions, provided the stomach does not lose its efficient motility. And here I would like to emphasize very strongly that any operation will hardly be a success if it is done when the state of gastro-ectasy has already been permanently established. There will be at this time quite a progressive state of marasmus, and the child will not stand any operation. The indication for the operation is already given in the second stage, when the empty stomach starts to show some degree of dilatation. And even without any dilatation, if, after evacuation and washing of the stomach for many days the child still continues either to vomit immediately after drinking or to retain a large part of the food for hours, while gaining very little in weight, then there is a proper indication for the operation. We must also bear in mind that such infants, even if we succeed in assisting them to bridge over the dangers of their early life, will in all probability be invalids all their life long—there will always be a misproportion between the stomach and pylorus, a gastric insufficiency with all its consequences upon body and mind! We should therefore not hesitate to operate, and should operate early; the operation should be performed while the stomach yet shows distinct and strong peristaltic movements. When the operation is done early the child will survive it; and when the hypertrophied pylorus is removed while the hypertrophied pyloric portion of the stomach is still capable of efficient activity, the motile function of the stomach will be restored in an ideal way.

There are at present on record 22 cases of congenital hypertrophic stenosis of the pylorus in infants, in which the diagnosis was established or verified by autopsies. They are as follows: Williamson[5] (1841), 1; Davoski[7] (1842), 1; Hirschsprung[6] (1888), 2; Peden[14] (1889), 1; Henschel[4] (1891), 2; Pitt[15] (1892), 1; Finkelstein[2] (1896), 1; Gran[10] (1896), 3; De Bruin Kops[16] (1896), 1; Thomson[17] (1896), 2; and (1897), 1; Schwyzer[18] (1896), 1; and (1897), 1; Soltau Fenwick[19] (1897), 1; Ashby[1] (1897), 2; Rolleston and Haynes (1898), 1. Finkelstein includes also a case of atresia of the pylorus reported by Loesschaft;[20] the atresia in this case, however, was within the duodenum, about six millimetres away from the pyloric valve. The degree of the stenosis given in these cases shows a considerable variation between the passability of a "fine probe," a "middle-sized probe," or even the "little finger."

R. Maier divides the cases of congenital stenosis of the pylorus observed by Landerer and by himself in adults into simple and complicated stenosis, according to the absence or presence of hypertrophy of the pylorus, and states that of their thirty-one cases eight were of the uncomplicated variety. It is a noteworthy fact that in the twenty-two cases of congenital stenosis of the pylorus in infants there is not one of the simple variety; all were more or less distinctly complicated by hypertrophy. This would seem to permit the interpretation that it is the rigid hypertrophy which makes the stenosis a fatal anomaly, while a simple congenital narrowness of the pylorus is distensible enough to be overcome by the natural or acquired forces of the stomach, and it is therefore not fatal. We can thus understand how an individual with a pylorus of only two millimetres in diameter (first case of Landerer) could attain an age of forty-five years. As to the hypertrophy in the complicated cases of Maier and Landerer, there is nothing in the way of assuming that it was not congenital, but acquired in the struggle of many years.

In this connection it deserves further to be pointed out that in many of the cases of hypertrophic stenosis in infants it is distinctly stated that longitudinal folds were present in the narrow lumen of the pylorus, which would seem to indicate that without the constricting effect of the surrounding hypertrophied tissue the mucous membrane alone would present a lumen larger than the actual diameter, though probably still narrower than in a normal pylorus.

As to the nature of the hypertrophy, the first writers on this subject, Williamson as well as Davoski, have described the conditions they found as hypertrophy of the submucous tissue. But this happened at such an early period in the microscopic era that we might yet, with Thomson, believe "that it was the muscular layer really which was affected." In our own case, however, according to the description of Dr. Prudden, the fibrous hyperplasia of the submucosa had a prominent share in the production of the thickening of the pyloric wall. Other writers, too, expressly report that all the layers of the wall evenly shared in the hypertrophy; for instance, Hirschsprung's first case, and Thomson himself reports in his third case that "here submucous connective tissue was greatly increased in amount." It seems to me, therefore, that Thomson goes too far when he asserts that "the whole narrowing of the passage seemed to be due to compression by the hypertrophied muscle," or that "in all the cases . . . the thickening of the pylorus was due mainly to great hypertrophy of the circular layer of muscular fibres." With regard to the participation of the muscle fibres in the hypertrophy, R. Maier divides into two forms the cases of complicated stenosis observed by Landerer and by himself. In the first form the duodenal end of the pylorus terminated in the shape of the vaginal portion of the uterus, while the gastric end appeared to be funnel shaped; in this form, Maier says, the hypertrophy is made up by the longitudinal muscle fibres. In the second form the pylorus appeared to be like an intermediate piece (Zwischenstück) between the stomach and duodenum, and consisted of a hyperplasia of the circular muscular fibres of the pyloric valve. The description of most of the cases of

the hypertrophic stenosis in infants seems to fit the first form of Maier; there is the funnel shape in one end of the pylorus and at the other end the shape of the vaginal portion of the uterus. Nevertheless, there is quite a general agreement among most of the writers that the hypertrophy is made up by the circular fibres. This seems to be the rule, to which there are so far only two exceptions—the case of Finkelstein and the second case of Hirschsprung. There is apparently room enough left for a further study of the anatomy of our cases.

As to the etiology of these cases, there is at present only the one hypothesis, which was put forward by Thomson and found favor with some of the subsequent writers. Thomson's theory is as follows: The primary lesion is "a functional disorder of the nerves of the stomach and pylorus, leading to ill-co-ordinated and therefore antagonistic action of their muscular arrangement." The fault in the nervous mechanism "is probably due in some way to delayed or imperfect development." "The antagonistic spasm of the pylorus and stomach must be connected with the passage downward of the large quantity of liquor amnii which the fœtus is believed to swallow during the later months of intra-uterine life." The muscular hypertrophy of the walls of the pylorus and stomach is "merely a secondary occurrence, being obviously due to abnormally increased activity, and this must have existed for a considerable period of the intra-uterine life."* This theory, I must confess, does not appeal to me as a very plausible one. It is apparently based upon the presupposition that the hypertrophy is confined to the muscular fibres, and that muscular hypertrophy can be due only to some sort of overaction. We have, however, already demonstrated above that in many of the cases the submucosa had a prominent share in the formation of the hypertrophy, and that in all the cases there was some degree of hyperplasia of the submucous tissue. A disorder of the nervous mechanism would not account for the hypertrophy of the connective tissues. Moreover, the assumption that a tonic contraction of the pylorus would lead to a hypertrophy of its own muscular coat seems to me to be without any foundation. A stricture of any kind leads to a muscular hypertrophy of the parts lying in front of it, but does not cause a muscular hypertrophy in the stenosed region itself. Pyloro-spasm in adults does not lead to hypertrophy of the pylorus, and cardio-spasm does not lead to muscular thickening of the cardia. Cicatricial stenoses in any of the muscular tubes of the body do not lead to muscular hypertrophy within the stricture. And even of the cases of congenital hydronephrosis with greatly hypertrophied bladder, which are quoted by Thomson as a parallel to our cases, the author himself says that "no organic obstruction exists to the passage of urine." A spasm of the constrictor vesicæ might lead to the hypertrophy of the detrusor, but not to that of the constrictor itself. Furthermore, admitted even that the overaction of the pylorus could lead to its thickening, how could the overaction cause a considerable elongation of the pylorus, which is observed in nearly all the cases? The thickening of the walls of the pyloric portion of the stomach is generally admitted to be an acquired condition, which, by the way, was not present in some of the cases. It seems to me that, by accepting the congenital muscular hypertrophy of the pylorus, not as a secondary occurrence due to some overaction, but as a primary lesion, simply as an embryological malformation, we make a much less risky hypothesis than that made by Thomson, which assumes, without safe precedent, an embryological disorder in the nervous mechanism of the pylorus, of which we know so little in the fully grown animal. And, after all, it is not simply a hypertrophy of the muscular tissue; it is the hypertrophy of all the tissues of the pyloric valve—it is, so to say, the hypertrophy of an organ. The pyloric valve has variable dimensions in different individuals, and it might occur that in one or the other individual it attained such a size as to be pathological in a teleological sense. The structure of the hypertrophied pylorus reminds one very much of the normal structure of the ileo-cæcal valve, in which, too, the longitudinal muscularis does not participate in the formation of the fold. In this connection it is worthy of mention that Brandt[21] described a case in which there was a hypertrophic stenosis of the pylorus as well as of the valve.

* Thomson was so sure of the correctness of his theory that he termed the condition "congenital gastric spasm." It is, however, always safer to derive a title from facts rather than from theories, which are always disputable.

IS RETROFLEXION OF THE UTERUS A DISEASE?

By THEODOR LANDAU, M.D.,

BERLIN.

If you were to attend a dinner in these times without appearing in evening clothes, the host, if he were your friend, would advise you to leave, in order to prevent the other guests ridiculing or pitying your poverty. If you appeared in a gynæcological society to-day and declared that the doctrine of retroflexions is nothing but a conventional humbug, you would be in the same position as the unfortunate man without his dress suit. You would be out of place in such a meeting, for in gynæcology there is also an aristocracy with fashionable ideas and dominating doctrines, to sin against which would be very much worse than to castrate all round without distinction. From a psychological point of view this is not surprising. Take from the gynæcologists their retroflexions, and you at once cut off a great part of their income. And when the money bag begins to decrease, the *Gemüthlichkeit* disappears and the critic is heard instead. Add to this the fascinatingly ingenious operations, so many of which are performed easily, elegantly, and at lightning speed. You will then understand why many admiring onlookers, bewitched by our magnificent art, are prone to forget that operations should not be per-

formed for their entertainment nor for the mere sake of operating, but for the benefit of the patient. Take, for instance, a simple operation which produces a change in the position of the uterus. All will agree to this operation who thereby increase their income, and who therefore believe gladly what is good for them—namely, the doctrine of school. But the doctrines of school are not always to be relied upon. We improve by observations made during our professional career.

If you wish my opinion on retroflexion, I will give it briefly in the following; for to dilate upon or refute what has been said on retroflexion would be a life-long task and a thankless one at best. I was fortunate enough to find the dominating views on this subject expressed in the "Transactions" of the German Gynæcological Congress, Leipzig, 1897. Those conclusions were the finding of a majority, although not a result of sound reasoning. It is true, indeed, that the opinions which have been brought before the profession at large are slightly mellowed; and occasionally a "still, small voice" is heard crying "Stop!" But, alas! the voice, even if it be heard, is unheeded, and the better views are disregarded, for they are not fashionable.

As we Germans are accustomed to consider everything from the time of Adam—not from Adams, the inventor of the first operations for deviations, but from the husband of Eve—I will observe briefly that the discussion of the value and importance of retroflexion is as old as gynæcology itself. Especially at the beginning of this century, in the Paris Academy of Medicine, absolutely opposite opinions were heard. Some agreed to one view, others to another. Regarding my own views, permit me to say that they are not new indeed, they are nothing else than stories of olden times.

Now as to the subject itself, and, firstly, the symptomatology. To-day all make a distinction between cases of simple retrodeviation and such as are complicated by inflammation of the adnexa. Even the adherents of the opinion that retroflexion is a disease admit that nearly half of all uncomplicated cases of retroversio-flexio show no symptoms, and especially that local symptoms in the pelvis may be absent. But, they say, if the local symptoms do not exist, there may still be reflex symptoms, and we, who are so stupid as not to believe in retroflexion, overlook the cause of these remote symptoms. Again, it has been remarked that retrodeviation sometimes remains symptomless for years, but later on may begin to cause symptoms. Why should we be called stupid? One speaker at the congress distinctly said that it is a logical mistake to make the treatment of a disease, known to exist, dependent upon the gravity or upon the presence of symptoms. If symptoms are produced by retroflexion, they are usually as follows: backaches, headaches, gastric symptoms, bearing-down feeling in the lower part of the abdomen, a diminution of walking-power, depression of mind, a host of nervous symptoms, constipation, dysmenorrhœa, painful and frequent micturition; and, in retroflexion of long standing, hemorrhages in the form of too frequent or too profuse menstruation; while in acute puerperal retroflexion there is a typical and prolonged menstruation. A less frequent result is ejaculation of the sperma, not into, but out of the vagina, sterility, abortion, and recurring premature labor. As anatomical changes are mentioned: catarrh of the cervix, hyperplastic endometritis, hyperplasia of the entire organ—that is, chronic metritis, which may be only partial—thickening of the vaginal portion, with large ectropium, oöphoritis, perimetritis. Well! well!

One author goes still further, and assumes that by the malposition there is not only produced a tendency to inflammatory processes around the uterus, but that the origin of ovarian tumors must be referred to the same cause. He argues as follows: Disturbances of the circulation and inflammatory troubles in the ovaries predispose to the formation of tumors. Retrodeviation produces disturbances of the circulation in the ovaries; therefore retroflexion produces ovarian tumors. Q. E. D.!

To be complete, I must add the anatomical changes in other organs produced by the retroflexion: Follicular catarrh of the rectum, cystitis, catarrhs of the upper urinary passages, bending of the uterus. When one enumerates all these symptoms attributed to retroflexion, one must admit it is a dreadful disease, producing in poor suffering women not only disagreeable symptoms, but also all possible conditions from albuminuria to insanity!

Suppose, then, that even once the connection of all these symptoms with retrodeviation has been proven. And how is the connection attempted to be proved? By the success of treatment. In what does the therapy consist? In the applying of one or all the methods invented up to the present day, from the pessary to the bloody operations. But one must not argue so, for in the subjects we are called upon to treat there are certain other substances in addition to muscular and cellular tissue which may be influenced by any therapy: *e.g.*, that white and gray substance which anatomists call nerves and central nervous system. Shall I remind you of those wonder doctors who call themselves homœopaths and cure with little sugar balls all possible and impossible aches? Shall I recall Lourdes or all the fashionable springs and miracle-working waters? Shall I also remind you that we have a threefold kind of hypnotism which we may conveniently classify according to its density? First, the aerial. This is the more common and is usually produced by a laying on of hands—by simple power of authority. Next, there is the fluid, by the giving of medicinal drops, drinks, and waters. And, finally, there is the solid form of hypnotism, *e.g.*, the application of pessaries and even of the knife. Do you not believe that Baker Brown, when he cut away the clitoris, even in cases of retroflexion, did not relieve many women of their troubles? And what shall be said about those cases in which pessaries have been put in or an operation has been performed, and the uterus has remained in its false position while all symptoms have nevertheless disappeared? How will you explain those cases in which, either by a pessary or by an operation, the malposition is redressed and yet all the troubles remain? Yes, in these cases all gynæcologists conclude that such are purely of nervous origin, and they are transferred to the department for incurables or handed over to the neurologists, who may cure them—if they can.

But a knowledge of the value of these processes cannot come from general philosophical considerations. It is to be derived only from the investigation of the individual case. While, for example, a discussion between two advocates on some point of law is, from the abstract nature of the case, inevitably interminable, the scientist, arguing from the single, concrete individual, will arrive—perhaps not quickly, but, without doubt, surely—at a definite conclusion. If, therefore, we take those authorities as our guides, who do not always speak deductively of groups, but who in all difficulties and complications consider each individual case on its merits and with unbiassed minds draw general conclusions from these collected single cases, we get quite another side of the picture and a very different view of these processes. Such authorities to-day are Leopold Landau, Theilhaber, Freudenberg, and very few others. Their views I will now give in the fewest words possible.

Uncomplicated retroflexion of the uterus is in itself no disease. It may possibly produce trouble during pregnancy, if the development of the pregnant womb does not, as usually happens in the great majority of cases, lift the organ out of the pelvis. If it remains incarcerated, there is material trouble in consequence of this imprisonment; viz., the well-known collection of symptoms included in the expression "incarceration of the pregnant uterus," which naturally call for treatment.

The mobile retroflexion may be congenital, and in that case it has no importance at all; or it may be acquired. Then it produces trouble, but only one symptom of a more general disease—of enteroptosis. But in these cases the gastroptosis, the coloptosis, the nephroptosis, and the hepatoptosis, the descent of the uterus and of the vagina, the abdominal hernia, etc., have each and all the same value.

Here we have a general relaxation of all organs covered by the peritoneum, and here, if our treatment is to be beneficial, we must restore the elasticity and the tension of the peritoneum and the abdominal walls, or we must repair them orthopædically by bands, pessaries, etc.

Fixed retroflexion is never a disease *per se*. It is only a symptom of existing pelvic peritonitis or pelvic cellulitis. Here it is not only a sign but an indicator, and for that reason we must take all pains to find it out. All the symptoms arise from the perimetritis or the inflammatory changes of the adnexa, the peritoneum, or the pelvic cellular tissue. Therefore, to describe the correct symptomatology and therapy of the fixed retroflexion of the womb would be nothing more or less than to describe the symptomatology and therapy of inflammation of all the pelvic organs, the pelvic cellular tissue and peritoneum included.

And so we have arrived at the important point which is the keynote of the proper understanding of retroflexion, and, therefore, retroflexion of the uterus requires observation and treatment only when it is associated with anatomical changes of other organs and tissues.

How, then, is it explained that so many troubles are referred to retrodeviation? Retroflexion is very frequent; but so are many other diseases. And when a woman refers her troubles to the pelvis and consults a gynæcologist, he should not forget or overlook the fact that she is liable to suffer from other than gynæcological diseases. If he examined the urine of patients more frequently, he would find evidence of cystitis and nephritis in a surprising number. If he searched for nervous symptoms, he would find nervous and hysterical patients. Were he to auscultate the heart, he would discover a number of heart murmurs. Nor should he forget that in the abdomen there are a stomach and an intestinal canal, both of which are exposed to so many insults and to functional and mechanical troubles, such as constipation and ulcer of the stomach. Let him remember the formation of stones in the kidneys and the gall bladder, so frequently found in females. Let him make palpation not only of the genitalia, but of the whole abdomen in women, who have become for some reason emaciated, and who in consequence of frequent pregnancies have lost the elasticity of the abdominal walls. And last, but not least, let him learn to make a careful examination of the genitalia and declare justly what exists. Then we shall guard ourselves and our patients from error, and we shall not endeavor vainly to obtain therapeutical results by wrong methods, while neglecting the proper means which would have the desired effect.

At present, only one word in regard to the therapeutical connection of retroflexion of the uterus and diseased appendages.

We can influence inflammatory processes of the other pelvic organs by treatment of the uterus, as little or as much as we can influence troubles in the brain by the application of blisters to the scalp. Indeed, we observe the brain infected by a wound of the scalp as often as the adnexa from the uterus. We must come directly to the disease, and treat it and not the symptoms. But while at present I will not speak on the treatment of the inflamed adnexa, a hint may not be out of place.

Nearly all genital diseases are systemic. One organ may be specially affected in a greater or less degree, but disease exists in them all to some extent. This is due to the intimate anatomical relation of the genital organs. Lymphatics and blood-vessels, by which the infection is propagated, are the same for all, and all the internal genitalia are covered by the peritoneum as a common protection. In this way the germs of disease are carried about and in most cases are not confined to one organ. The entrance of the offending agent may be ascending, as in the case of the gonococci and staphylococci; or descending, as, for instance, in the intestinal bacteria. If to these you add the tubercle bacillus, you will admit there is a common death for all the genitalia at once.

Therefore, if you would try to cure retroflexion alone in a case of pelvic inflammation, you would do the same as if you would search for a remedy against the bronchial sounds in a case of tuberculosis. Only that man will be right who endeavors to cure the tuberculosis without heeding the symptoms.

In conclusion, I would add that unless we seek diligently for associated troubles, we are not doing our full duty either to our patients or to ourselves.

THE VALUE OF ELECTROLYSIS IN THE TREATMENT OF URETHRITIS CHRONICA GLANDULARIS.

By GEORGE THEODORE MUNDORFF, M.D.,

NEW YORK.

The object of the present paper is to call attention to the results following the employment of electricity in the treatment of chronic glandular urethritis. Some observers, it is true, have already practised this method of attacking diseased urethral glands, but none, so far as the writer knows, has published desirable and complete reports of his observations. In the past year, during the writer's connection with the genito-urinary surgical clinic of Dr. H. Wossidlo, in Berlin, a series of experiments was instituted for the purpose of determining the true value of electrolysis in the treatment of this particular pathological condition, and I now desire to present a somewhat detailed account of the results obtained.

Mention has been made of a special form of chronic urethritis. It may perhaps not be unacceptable to describe briefly what is understood by chronic glandular urethritis. Oberlaender, in his work, "Lehrbuch der Urethroscopie," recognizes two varieties of chronic urethritis, and names them respectively "urethritis chronica infiltrativa" and "urethritis chronica glandularis." In the first-named form the pathology consists in a chronic inflammation involving the urethral mucosa pure and simple, while in the latter form the inflammatory process is limited chiefly to the minute mucous glands scattered over the mucous membrane lining the pars cavernosa urethræ. By employing the urethroscope, these two conditions may be readily differentiated, as follows: In the infiltrated form the mucosa is found to be the seat of a chronic inflammation. The small glands distributed over its surface need not be involved in this inflammatory process at all, but may remain normal. In the glandular form we have to do with a condition in which the mucous

membrane around the orifices of Littré's glands and the crypts of Morgagni is inflamed and swollen. Occasionally the ducts of these glands become occluded by plugs of secretion, converting the little follicles into small cysts. The guilty factor in many cases of intractable gleet is simply the unrecognized existence of one or more diseased urethral glands.[1]

Recognizing a condition in which the glands are simply involved in the inflammatory process, it is but natural that one would desire to treat them alone and not expose normal tissue to unnecessary irritation. Various methods to apply local treatment have been advocated. Some authorities have recommended the use of chemical caustics, others have claimed that good results follow the intraglandular injections of therapeutical agents, while a few have lauded the employment of the galvanic cautery. It was Oberlaender[2] who, in 1889, first suggested electricity to destroy chronic inflamed urethral glands. For this purpose, he constructed a unique contrivance in connection with his urethral endoscope. Notwithstanding this, in 1892[3] and in 1894[4] this authority dismisses the subject of intraglandular electrolysis with the remark that by its use cure is retarded four or five weeks. In 1893, Kollman[5] introduced a set of instruments including an electric sound for intra-urethral work. This sound consists of a slender platinum rod, about six inches in length, and, with the exception of its point, is insulated by means of an India-rubber covering. Two forms are made, the difference existing in the distal extremity. For the purpose of destroying Morgagni's crypts, a sound with a blunt end is employed, while in the case of diseased Littré's glands a sharp-pointed one is used. The writer has found it rarely necessary to employ the blunt sound, the sharp end of the other answering for both.

In the opinion of the writer, notwithstanding the unfavorable result in a few cases, electrolysis is a valuable adjunct to the list (which perhaps is already too long) of remedies for the treatment of the glandular form of chronic urethritis. This therapeutical agent is certainly more within the control of the physician than any other form of treatment, and, if its application be cautiously performed, can result in no harm. For weeks one may inject solutions of nitrate of silver or other astringents into the urethra, and still produce no retarding effect upon the progress of the disease. The internal administration of drugs has proved of little or no benefit. The use of the galvanic cautery is dangerous, requires a local anæsthetic, and causes unnecessary destruction of tissue. In the case of electrolysis, the operation is painless and does not require any topical anæsthesia. Occasionally a patient complains of a slight burning sensation, but it is certainly not more than that often following urethral injection of a mild solution of nitrate of silver. The method pursued is as follows:

A Kollman electric sound is affixed to the negative pole of an ordinary galvanic battery, while a suitable sponge electrode is attached to the positive pole. After a careful endoscopic examination of the urethra, the number and location of the diseased glands are noted. It is beside the purpose here to examine the question as to the relative merits of the various forms of urethroscope now in use, but a word or two may be said as to the necessity of performing urethroscopy in all cases of urethral disease—excluding, of course, acute urethritis. The value of this method of examination cannot be too highly estimated. It should be invariably done, for by no other means can one gain an accurate knowledge of the conditions present. The practice of trying to elicit localized points of tenderness by means of bougies certainly cannot compete with a method of examination by which one sees directly what the trouble is and where it lies. In the experiments upon which this report is based, the Nitze-Oberlaender urethroscope has proven by far the more serviceable one, both in illumination and in convenience of handling. Owing to the direct light obtained through the agency of this endoscope, the minute glandular openings are more readily seen and the condition of the glands themselves is better appreciated. These certainly are facts having much weight in the proper treatment of a urethral disease. Placing the question of illumination aside, the unique construction of this apparatus allows one better to employ his intra-urethral instruments.

It is best for the physician to stand to the right of the patient (the patient being seated in a reclining-chair), for reason that the steps necessary to the operation can be followed more conveniently. The moistened sponge electrode having been applied to either the perineum or abdomen—preferably to the latter, as here it does not hinder the operator in his work—the endoscopic tube is introduced to the bulbous portion of the urethra, and then slowly withdrawn until a diseased glandular opening comes into view. The tube is now held steadily with the left hand, the sound is thrust directly into the opening of the duct, and the electric circuit is closed. In a few seconds the following phenomenon is observed, showing that the electrolytic action is in play. A ring of grayish-white foam is seen to form around the electrode, somewhat obscuring the field of operation. At this stage it is best to disconnect the current, remove the electric needle, and then, by means of a cotton swab, dry the mucous membrane. The needle is not to be withdrawn from the tissues until the current has been disconnected at the battery, thereby avoiding a disagreeable shock. The operation can then be continued. Regarding the strength of the current and the duration of its application, Kollman advises an amperage of four or five milliamperes, and a *séance* lasting three minutes for each gland. In the cases reported herewith, the writer found it hardly necessary to demand more than twenty seconds thoroughly to destroy a gland. Still, this question is largely one of experience, and dependent upon various circumstances, such as individual endurance, the condition of the urethra, etc. If electrolysis be continued too long, more destruction is produced than is really necessary for the complete obliteration of the gland and there is more likelihood of the formation of dense cicatrical tissue. Case II. sufficiently proves the danger of too long an application. In this case a firm stricture developed, which demanded energetic treatment for its dissolution. To destroy more than three glands at one sitting is not recommended, nor is it advised to repeat the operative procedure in less than ten days, for the reaction excited is by no means a slight one. Two or three injections with some non-irritating solution will assist in reducing the inflammation. If the reaction be in any way severe, which event is revealed by an increased purulent urethral discharge, anterior irrigations with a solution of silver nitrate (1 in 1,500 to 1 in 1,000) should be made every two days until the discharge diminishes. Of course, during this period—which may extend over four weeks—electric treatment is absolutely contraindicated. In the cases accompanying this report, no medication other than the injection of cold distilled water was employed from the beginning of this particular form of treatment to the discharge of the patient.

[1] Wossidlo: "Practicable Urethroscopy," MEDICAL RECORD, September 7, 1895.

This precaution was taken in order to avoid the possibility of assigning beneficial results—if there were any—to the electric current, when the real cause might lie in another direction. Electric interference might prove more efficient, however, if from its institution it were combined with occasional injections of a mild astringent solution. There being in the majority of cases of chronic glandular urethritis an accompanying periglandular infiltration, it may be necessary to institute a course of treatment by dilatations previous to destroying diseased urethral glands by electrolysis. And in those cases in which the urethroscope shows dense cicatrization in the neighborhood of obliterated glands due to the action of the electric current, subsequent dilatation is indicated. In connection with these gradual dilatations, urethral injections are to be made every other day. These indications will be summed up at the end of this article.

The cases reported herewith were cases of true chronic urethritis due to the presence of the gonococcus of Neisser. In one or two cases this bacterium was not discovered, although examinations of the discharge issuing from the meatus, of the secretion obtained from several diseased urethral glands, and of the shreds floating in the urine, were repeatedly made. Still, it is quite possible that the specific germ was present in these cases and the underlying cause of the chronic urethral inflammation. Of the following seventeen cases, twelve occurred in polyclinical practice and five were under private care.

Case I.—P. R——, aged twenty-six. First attack of gonorrhœa in 1889. Second attack in 1893. Both attacks treated with urethral injections. Applied for treatment, December 7, 1896, complaining of a urethral discharge in the morning and the continual presence of shreds in the urine. Urethroscopy revealed glandular and periglandular infiltrations. Treatment: anterior dilatations every ten days, and urethral injections of nitrate of silver, 1 in 1,000, every two days. The conditions remained the same until May 11, 1897, when three urethral glands were destroyed through the agency of the electric current. Reaction was severe. Anterior irrigations with distilled water. Patient irregular in attendance. On July 7th, three more glands destroyed. Discharge diminishing. Urine clear. August 11th, two remaining diseased glands destroyed. Discharge ceased. Urine clear. Patient has been now six months under observation, and during this time all signs of urethral disease have remained absent. Cure.

Case II.—H. R——, aged twenty-nine. First gonorrhœa in 1891, second attack in 1892, and third in 1894. Applied for treatment, December 1, 1896, complaining of all the symptoms of "gleet." Urethroscopy revealed urethritis chronica infiltrativa et glandularis. Treatment: injections of silver nitrate every two days, and anterior and posterior dilatations every ten days. No favorable progress. September 3, 1897, four glands destroyed. Slight reaction. Injections of distilled water. September 28th, three glands destroyed. Severe reaction. October 26th, a tight stricture diagnosed. Upon the patient's application for treatment in December, and during the whole period of attendance at this clinic, no stricture was ever present. This stenosis being regarded as one probably due to a very much swollen mucous membrane, it was decided to wait for further developments. During this time, distilled water injections. January 1, 1898, urethroscopy revealed a tight organic stricture, made up wholly of the dense cicatrices of destroyed glands. Regular dilatations every eight or ten days, and silver-nitrate injections. February 15th, patient still under observation. Stricture undergoing resolution. Symptoms of chronic urethritis still present Failure.

It is plainly evident that this stricture developed in consequence of a too energetic electrolytic treatment. In this case an amperage of eight milliamperes was used, and the electric current was permitted to act for about thirty or forty seconds for each gland. The reaction was severe.

Case III.—B——, aged twenty-seven. Contracted gonorrhœa in August, 1896. Applied for treatment, December, 1896, and gave evidence of a chronic urethritis. Urethroscopy revealed urethritis chronica infiltrativa et glandularis. After the regular anterior and posterior dilatation treatment had been pursued for one year, no favorable result being observed, it was decided to try electrolysis. December 1, 1897, one gland destroyed. Moderate reaction. Distilled-water irrigations. December 15th, the remaining three diseased glands destroyed. Violent reaction. Discharge very profuse; shreds increased in number. January 30, 1898, changed treatment. Failure.

Case IV.—H. R——, aged twenty-two. First gonorrhœa in 1895. Second attack six weeks ago. Applied for treatment, May 15, 1897. Urethroscopy revealed urethritis subacuta glandularis. Janet treatment pursued. August 1, the discharge still continued. August 9th, two glands destroyed. No marked reaction. Irrigations of distilled water. August 20th, one gland destroyed. No discharge; clear urine. Two months later, discharged cured. Cure.

Case V.—J. D——, aged twenty-seven. Contracted his first urethritis in April, 1897. Applied for treatment in August, 1897. Urethroscopy revealed urethritis subacuta glandularis. Treatment, daily injections of a two and one-half to three per cent. solution of argonin. No favorable progress after several weeks of this treatment. October 11th, two glands destroyed. Moderate reaction. Injections of distilled water. In a few days, morning discharge ceased, and had not returned at the time of the patient's discharge, November 2d. Cure.

Case VI.—A. K——, aged twenty-nine. First gonorrhœa in 1896. Second attack six weeks ago. Applied for treatment, August, 1897. Urethroscopy revealed urethritis chronica glandularis. Regular dilatation treatment was instituted and followed until October 10th. No favorable result. On this day two glands destroyed. Slight reaction. Discharge diminishing. Distilled-water injections. October 20th, six glands destroyed. The following day, remarkably enough, there was absolutely no reaction. Discharge ceased. Patient discharged, December 1st. Cure.

Case VII.—A. M——, aged twenty-seven. First gonorrhœa in August, 1896. The following month, gonorrhœal arthritis. Applied for treatment, August, 1897, and gave a history of "gleet." Urethroscopy revealed urethritis chronica glandularis. Regular dilatation treatment until September 1st. September 2d, owing to the fact that patient showed absolutely no favorable progress, two glands were destroyed. Slight reaction. Distilled-water injections. In a few days discharge ceased. Kept under observation for three weeks and then discharged cured. (In the early part of October the patient returned to the clinic with an acute gonorrhœa.)

Case VIII.—H. H——, aged thirty-one. Applied for treatment, August 31, 1897, and gave the following history. Six months ago contracted his first gonorrhœa. Was treated with urethral injections and the regular introduction of bougies. Urethroscopy revealed urethritis chronica glandularis. The following day, one gland destroyed. Slight reaction. The discharge then ceased. During the next three or four weeks, absolutely no discharge and the urine remained clear of shreds. About the latter part of Sep-

tember, urine again contained shreds and patient complained of a urethral discharge. Urethroscopy revealed six diseased glands. (In the first urethroscopy but one diseased gland was discovered.) September 29th, six glands destroyed. Severe reaction and very profuse discharge. Urine contained numerous shreds. Distilled-water injections. No improvement being noticed, treatment was changed, October 22d, to the regular dilatation treatment. Failure.

Case IX.—A. K——, aged twenty-nine. Applied for treatment, November, 1897, and gave a history of acquiring his first attack of urethritis six weeks ago. Urethroscopy revealed urethritis chronica glandularis. November 8th, two glands destroyed. Slight reaction. Discharge diminishing. Distilled water injections. November 20th, six remaining glands destroyed. Slight reaction, followed by clear urine and disappearance of discharge. Patient discharged cured six weeks later. Cure.

Case X.—T. V——, aged twenty-six. Applied for treatment, January 6, 1898, and gave history of two attacks of gonorrhœa—one in 1891, the other in 1895. Had all the symptoms of "gleet." Urethroscopy revealed a urethritis chronica glandularis. January 12th, two glands destroyed. No reaction. Disappearance of all symptoms of chronic urethritis. Patient discharged cured two weeks later. Cure.

Case XI.—E. S——, aged twenty-nine. Applied for treatment, November 11, 1897. Patient acknowledged three or four attacks of gonorrhœa and having undergone treatment for syphilis. Last attack of urethritis six months ago. Urethroscopy revealed urethritis chronica infiltrativa et glandularis. November 13th, one gland destroyed. Violent discharge and severe reaction. Notwithstanding two weeks of daily urethral injections of distilled water, discharge continued to be profuse. The treatment changed to injections of protargol. Failure.

Case XII.—P——, aged twenty-five. Applied for treatment, January 5, 1897, and gave a history of two attacks of urethritis—one a year ago, the other six months later. Patient complained of symptoms of "gleet." Urethroscopy revealed urethritis chronica glandularis with extensive periglandular infiltrations. The regular dilatation treatment followed for three weeks. On the 20th, three glands destroyed. Discharge diminished and urine became clearer. A week later, dilatation treatment again begun and continued until the middle part of August. Highest dilatation, 42. On August 31st, four glands destroyed. Slight reaction. Injections of aqua destillata. On the 28th of the following month, three glands destroyed. No reaction, no discharge, and no shreds in urine. Patient kept under observation for six weeks and discharged cured on November 25th. Cure.

Private Patients.—Case XIII.—W. S——, aged thirty. Applied for treatment, July 8, 1894. Gonorrhœa a year ago, followed by several relapses. Complained now of symptoms of "gleet." Urethroscopy revealed urethritis chronica infiltrativa et glandularis. Dilatation treatment instituted. On November 22d, several (number not noted) glands destroyed. Discharge ceased and shreds in urine disappeared. Patient discharged cured, December 30th. Cure.

Case XIV.—B. D——, applied for treatment, February 2, 1895. First attack of gonorrhœa in April, 1894. Treated with urethral injections and the regular introduction of sounds. Complained of discharge from urethra and shreds in urine. Urethroscopy revealed urethritis chronica infiltrativa et glandularis. Regular dilatation treatment instituted and followed until April 2d. Several glands destroyed. Profuse suppuration. Discharge did not diminish, notwithstanding all methods of treatment to check it. Treatment changed to Janet's irrigations with permanganate of potassium. Failure.

Case XV.—X. S——. Applied for treatment on June 20, 1897, and gave a history of three attacks of gonorrhœa. First attack in 1892; last attack in 1894. Complained of symptoms of "gleet." Urethroscopy revealed urethritis chronica infiltrativa et glandularis. For five months patient received regular dilatation treatment, but without success. November 14th, two glands of Morgagni destroyed. No reaction, but the discharge did not cease. Several weeks later, the dilatation treatment again begun and followed. Failure.

Case XVI.—Von S——. Applied for treatment, July 17, 1897, and gave a history of suffering from chronic urethritis for one year. Urethroscopy revealed urethritis chronica infiltrativa et glandularis. Regular dilatation treatment instituted and followed until January 16, 1898. Three glands destroyed. No reaction. Discharge diminishing. Injections with distilled water. January 26th, three glands destroyed. No reaction, discharge ceased, and shreds in urine absent. Patient discharged cured, February 2d. Cure.

Case XVII.—L. M——. Applied for treatment on December 8, 1897. First gonorrhœa twelve years ago, followed by several "relapses." Complained of symptoms of "gleet." Urethroscopy revealed urethritis chronica infiltrativa et glandularis. Regular dilatation treatment followed. No progress to a cure. February 25, 1898, three glands destroyed. Moderate reaction; the discharge diminishing somewhat. Still (March 1, 1898) under treatment.

Judging from a close study of the above seventeen cases, as well as from an experience derived from observation of nearly four hundred and fifty cases of chronic urethritis in which different forms of treatment were pursued, the writer arrives at the following conclusions:

(1) In all cases of suspected urethral disease (excluding cases of acute urethritis) a careful urethroscopic examination should precede treatment.

(2) As a rule, all forms of chronic urethritis can be cured by regular dilatations and urethral injections of a silver-nitrate solution.

(3) Electrolysis is indicated only in the glandular form of chronic urethritis.

(4) Electrolysis will cure the larger proportion of chronic glandular urethritis.

(5) If electrolysis fails, the dilatation treatment is indicated.

(6) In some cases of chronic urethritis, dilatation treatment preceding electrolysis will prove beneficial.

(7) In those cases in which firm and dense cicatrices have developed in consequence of electrolysis, regular dilatations should be proceeded with.

(8) During treatment, endoscopic examinations of the urethra should be regularly made, controlling thereby, under the direct guidance of the eye, the progress of the disease, and, according to the conditions found, modifying the treatment.

I am deeply indebted to my friend, Dr. H. R. Wossidlo, of Berlin, not only for permission to publish the histories of the foregoing cases, but also for many valuable hints and suggestions in the preparation of this article.

268 East Seventh Street.

Ignored Syphilis Complicated by Septicæmia.—Latent syphilis may be complicated by secondary septicæmia upon which quinine and salicylate of sodium fail to act. The condition improves immediately, however, when the primary disease has been treated by antisyphilitic remedies.—Surmont and Patoir.

THE CONTROL OF TUBERCULOSIS.

By H. H. SIMERS, M.D.

RAVENNA, OHIO.

Of all historic diseases which have afflicted mankind, no continuous disease has been less subject to control than tuberculosis. There have been epidemics or endemics that were more fatal or less subject to control for short periods of time. But these have been only for short periods. These diseases die out for want of fresh fuel, or their very contagiousness has demanded great effort which has resulted practically in control.

With tuberculosis the case is different. This is a disease with which we all are practically familiar—one which every medical man thinks he understands. The very clearness of apprehension with which he thinks he sees leads him blindly on in treatment or prevention. Hence no stop or cure.

It is a common impression that tuberculosis is due to a germ. If true, the germ being killed, the disease would at once cease. Methods of destroying germs are familiar to all. It is plain to the ordinary observer they are of little value. Germicides *per se* being valueless, it enters the minds of some that perhaps a condition of the system may be induced that will prevent the entrance of germs, or—may be better—will not allow their growth. Germ cultures are procured, and their alkaloids used to fortify the system or render it immune. With a painstaking accuracy worthy a better result, these germs are isolated, cultivated, and the alkaloids injected for this purpose.

The result is before us. Is tuberculosis lessened by injections of these cultures? There are many occupying chairs in medical colleges who would be pleased to answer in the affirmative, but facts do not bear out the assertion. Instead of boldly saying no, which would be the writer's course, the attempt is made to waive a direct answer to the question and encourage a hopeful view for the future. At the same time these teachers are continually instructing in methods which have long since proved practically *nil*. Is such instruction a benefit? Finding it impossible to kill the germs in the air or in the person without injury, finding immunity largely an imaginary quantity, men have in some quarters advocated germ-proof houses. It is soon seen by all except a few fanciful scientists that even these germ-proof buildings could be of little value.

The question now arises: If present notions prevail, how soon will tuberculosis be under control? No one can clearly answer, for no one knows. Under the circumstances, would it not be wisdom carefully to investigate the cause of disease and see if there be not some other connecting or underlying condition which allows the living tubercle bacillus to enter one's system and grow? If such condition be found, would it not be further wisdom to inquire if this condition is always present in the growth of tubercle bacilli in the human organism? If always present, would it not yet be further wisdom to ascertain if this condition cannot be removed and thereby prevent the entrance of a growing bacillus in one's system? If this condition exists, is always present, is removable, we hold in our hands an effectual weapon for the prevention of tuberculosis.

The writer claims that here is a succession of facts the force of which cannot be weakened by any argument. In other words, here lies a chain of reasoning on which the law of tuberculosis is based. This law is based on facts as immutable as is any law of Kepler or Newton. This law must stand. What is the law of tuberculosis? The death rate from tuberculosis is in direct ratio to suspension of atmospheric influence.

Having laid down a law of tuberculosis, let us now critically examine the facts on which this law is based. My attention was called to these many years ago. The first published article bearing on the subject is found in the December number of the *Cleveland Medical Gazette*, 1890. Phthisis pulmonalis is here spoken of as a zymotic disease. Medical experts had so placed it, and this opinion was accepted without question. Upon investigation the contagiousness of the disease was in doubt. It was found there are certain conditions of the system in which one apparently takes the disease. There are other certain conditions in which one does not take the disease. The question arose: On what does the contagiousness or non-contagiousness of tuberculosis depend? In answer to this, it is seen that certain animals are affected and the same animals are not affected, according to the condition in which they are housed or kept. Some in authority have lately asserted that food or diet has as much to do in the origination or starting of tuberculosis as has the atmosphere. The writer thinks that in this statement there is a misconception. It is not the atmosphere *per se*, but suspension of atmospheric influence that induces the condition or disease. Food or diet, according to quantity and quality, may improve or weaken the physical or mental condition. This, I think, is about all. Suspension of atmospheric influence, whether the animal be weak or strong, will produce a condition of the system which allows the tubercle bacilli to enter and grow.

While suspension produces a condition favorable to the growth of a germ, food produces simply a strong or weak condition of the system and has no relation to the germ's growth whatever. This, I think, is a marked difference, and one which even late observers have entirely overlooked. Again, it is evident that if the basic facts be changed, the law depending on those facts must be worded differently. This accounts largely for the change made in the law.

Another fact may be referred to at this time. It is very difficult for some to enter into a discussion or investigation in which figures or mathematics are used. In order to accommodate this class, the law is stated in the simplest language possible. The writer feels assured that those who impartially investigate the subject will find the conclusions accurate.

With this simple law before us as demonstrated, with the deadly disease before us as seen, it is the writer's hope and belief that much may be accomplished in a practical way by simply living in accord with the teachings of this law; by avoiding in every possible way the suspension of atmospheric influence. A deadly enemy is before us. In every engagement thus far we have met defeat. Let us train our guns to do the most effective work. Before entering an engagement, it is always well to take an account of the character of weapons to be used. One great difficulty in the recent past has been that the bacteriologists have taken upon themselves the entire work. This I think is a mistake. Bacteriology is one arm of the medical service. Its work along its own line is of great value; its work in other lines of no value whatever.

To illustrate: We have many ships in our navy—battleships, cruisers, torpedo boats, etc. Suppose a captain of a torpedo boat should say, "My boat will act as a battleship." Or the captain of a battleship should say, "My boat will act as a cruiser." Or the captain of a cruiser should say, "My boat will do the entire work; the rest of you may remain idle." What would be the condition of the navy? Any one could see that the service would be of no practical benefit whatever. We might as well do without a navy as to have one boat arrogate the entire service to itself. Thus with bacteriology. Bacteriology has been pushed forward to the exclusion of everything else. I trust some of my contemporaries will see the force of this assertion.

There is another insuperable difficulty which bacteriology has met in the battle with tuberculosis. It is assumed that tuberculosis is a germ disease. If it were a germ disease, rationally considered, it could be met with germicides or the alkaloids of germs. It not being a germ disease, rationally considered, germicides or alkaloids of germs would be of no value. Whether the disease be due to a germ or not, I leave to an intelligent profession; this much is certain, bacteriology has thus far found no cure for the disease. The same may be said of other methods of treatment. The writer believes that the secret lies in recognizing the cause of tuberculosis. It is plainly evident, if the cause of tuberculosis be suspension of atmospheric influence, no line of treatment could cure without first recognizing the cause and removing it. Even then, if there be destruction of tissue, no treatment could restore tissue lost. These facts must be taken into consideration when talking of cure. So that he who asserts he has a cure for tuberculosis either falsifies or is ignorant.

There being no cure for tuberculosis, it remains to be asked: In what way can we arrange our forces most effectually to battle with the disease? To the writer it seems clearly evident that the control of the disease must be largely along the line of prevention. Now do not misapprehend. The writer believes that open air and constitutional treatment are of great value. In truth, in conjunction, they are the best treatment of tuberculosis known to the science of man. At the same time, to repeat a well-worn aphorism: "An ounce of prevention is worth a pound of cure." There is no cure for tuberculosis. There is prevention. If prevention succeeds, there is no need of cure. To-day this hydra-headed disease exists on every hand. There is need of prevention and there is also need of treatment. Insidious and deadly in its nature, say not to the afflicted that there is no value in treatment. There is value in treatment. But if cure be perfected, treatment must be given in the precedent state or incipient stage of the disease. Then there is cure. But, as said in a previous article, if there be disorganization or breaking down of lung tissue, this tissue can never be restored. Yet even in this condition treatment is of value, and by its judicious employment life may be prolonged and aid and comfort given the afflicted. This alone is certainly worthy our consideration.

To speak directly of prevention, the first step to be taken is to remove the cause of the disease. If the disease be due to suspension of atmospheric influence alone, the first step in prevention is to remove the suspension. Without this, nothing can be accomplished. With this, much can be accomplished. If due to heredity in conjunction with suspension, here the battle must continue as long as life lasts. Heredity is an entity of the parents, and must be controlled in the rising generation by proper marriage. Let no one marry into a consumptive family, should he desire healthy offspring. Evidently the marriage relation is a serious one, if we look at it in the light of transmission of disease. Every one who asks in marriage should have a clear health register, and he should expect the same of his partner. Without this, tuberculosis will remain a disease in the human family to the end of time. With this, tuberculosis can be controlled.

In a recent session of our legislature, some one introduced a bill to regulate marriage. What became of the bill, the writer only conjectures. One thing is known—the way in which the measure was received. Some spoke of it as ahead of the times; others as visionary, unnecessary, ridiculous, etc. It is not worth while to discuss the merit of this particular bill. This much is certain; in the years to come some measure of this character will be enacted to prevent disease. Education must ever precede legislation. It is education to-day, legislation to-morrow. In this way, step by step, the human family has risen in civilization. The laws of Ohio to-day could not be enforced in present China. The laws of Ohio, it is hoped, will be changed for the better in the years to come. True, it is difficult to legislate on marriage. To say one must or must not is somewhat arbitrary. Is it not best to do so? When one is educated to select only the best in marriage, it is more largely a matter of choice or judgment and less one of impulse or emotion. Not long since a man of this city, pointing to a deformed child, said: "If nature could give me no better body than has that child, I would ask to be shot." Please reflect! What was nature's act other than the volition of the parents? Why not legislate?

Reverting to suspension of atmospheric influence, this may be induced in many ways. The following classification has already been given the public, but as it presents the subject in the clearest light possible it is repeated here.

SUSPENSION OF ATMOSPHERIC INFLUENCE.

From without.	Impure atmosphere.	Ill ventilation, vocation, etc.
	Impoverished atmosphere.	Overheating rooms, improper ventilation, etc.
From within.	Defective lung tissue.	Original. Heredity.
		Acquired. Disease, exposure, etc.

To explain more fully, suspension takes place in two ways—from within and from without.

From within through original or acquired lung tissue. Though the scalpel or microscope may detect no difference in lung tissue, it is observed that children of consumptives take the disease more readily than children of the healthy. Why? Defective lung tissue—heredity. Such children will tolerate no confinement. Confinement to them means death from tuberculosis. These children die from the disease, while other children escape—ventilation, food, physical exercise, etc., being the same; thus showing that there is a difference in the organism or lung tissue. It is also observed that those having stenosis of the air passages, whether congenital or acquired, are more subject to tuberculosis. Why? Suspension of atmospheric influence. In some of these cases operation to remove the stenosis is beneficial. In all, there should be perfect ventilation.

There are certain diseases which tuberculosis is pretty sure to follow if precaution be not taken, viz., measles, pertussis, etc. Why? Defective lung tissue—acquired. Suspension of atmospheric influence due to thickened lung tissue. What precautions are necessary? Perfect ventilation during sickness and recovery.

From without, through impure or impoverished atmosphere. Every observer has noticed that there are two classes in particular who suffer much from tuberculosis—they whose vocation or calling keeps them continuously in the dust and they who suffer from confinement in ill-ventilated rooms. In the first class there is suspension from lodgement of dust particles in the air cells of the lungs or from mechanical irritation of the same—one or both, commonly both. What is the preventive? Avoidance of the irritating dust. (1) Change of vocation; (2) wearing of a dust protector; (3) elimination of dust by a dust collector.

If heredity be a factor, the first method should be adopted. No one should engage in or follow an unfavorable pursuit if the subject of hereditary influence. Though the usual precautions were taken, the probability is he would die of tuberculosis. If the subject be vigorous and have a good family history, he may follow the vocation of his choice. In this case a dust pro-

tector is of service, but unequal to a dust collector. In all shops where there is an irritating dust these collectors should be obligatory.

We now reach the topic of impure or impoverished atmosphere. This has been explained elsewhere (*Lancet-Clinic*), but a word or two in this connection will not perhaps be out of place. We, as Americans, are living in homes many of which are warmed by furnace heat. In all homes there is artificial heat for a part of the year. In these homes the atmosphere is at times impoverished. As a result, the occupants suffer largely from respiratory and constitutional disease. Tuberculosis is of this number. It is prevalent and deadly. Treatment is of little avail. Prevention is of value. The preventive, the writer is inclined to believe, consists in a stove or furnace of at least double the size or capacity of the one ordinarily used. It takes no more fuel, the heat is more constant and even, and the stove or furnace lasts longer. There is therefore no greater expense in the end. There is an assurance of better health. The danger in cold weather is that too much oxygen is withdrawn from the room to support combustion, and not enough air is let in to replace the oxygen abstracted. Suspension of atmospheric influence is induced. In this way plants and animals alike suffer.

There is another factor which should engage our attention. I refer to the irritant dust of soft-coal stoves and furnaces. In the present arrangement of these, nearly all give off an irritant dust, smoke, or vapor. Irritation of the throat, fauces, and bronchial tubes commences soon after their use. This should not be. The draught should be perfect, so as to allow no dust in the room. If it is not perfect, there is suspension of atmospheric influence because of the irritant dust; also because of the lack of oxygen in the air. Consequent tuberculosis. When these facts are clearly understood and acted upon, the writer feels satisfied the death rate from tuberculosis will be much diminished. If true, this statement is worthy of consideration. In the above I refer to the atmosphere as found in country homes and villages. In large cities, as a rule, it is very much more impure. Large cities are railroad centres, contain the factories, workshops, etc. There are, of necessity, great volumes of smoke. At times the outdoor air is almost unendurable. Science can and no doubt will soon remove this smoke nuisance of cities.

There are other factors, not mentioned, in cities which contaminate the air and render it unfit to breathe. I pass over these. One or two others I mention which aid respiration and whose absence makes breathing more difficult. I refer to public baths and gymnasiums.

To conclude, if the person be kept clean, a certain amount of daily physical exercise be taken, and pure air constantly inhaled, there is no danger whatever from tuberculosis if there be no heredity. Tuberculosis can be controlled.

Hot Oil as a Sterilizer.—According to *The Hospital*, hot oil is more efficient than boiled water in sterilizing instruments. Olive oil at a temperature of 320° F. to 356° F. acts very quickly and with great power. To obtain complete sterilization of the instruments it suffices to dip them for an instant into the hot oil, and in the case of syringes it is sufficient to fill them twice with oil at the temperature mentioned. The temperature of the oil of course may be determined by the thermometer, but Professor Wright, of the Netley Hospital in England, suggests the simple although somewhat rough-and-ready method of dropping a crumb into the oil, which becomes brown and crisp as soon as the required temperature is obtained.

DIVULSION OF THE SPHINCTER ANI AS A THERAPEUTIC AGENT.[1]

By J. N. BAUGHMAN, M.D.,
EVANSVILLE, IND.

The majority of rectal diseases are situated either at the sphincter or within one or two inches of it, and all of this part of our anatomy is very liberally supplied with nerves, and all from the same source, so that an irritation in any part of the rectum will affect the entire rectum and sphincter. Any irritation to the nervous supply of the sphincter ani will result in its spasmodic contraction, and thus it may be seen that if we can put this muscle entirely at rest we shall gain an important point in our treatment of most rectal diseases.

We take, for instance, a case of hemorrhoids, either internal or external, but more especially internal, and when the swollen and inflamed tumors come down within the grasp of the sphincter muscles they are caught, and the constriction caused thereby produces an amount of congestion and further inflammation in the pile tumor that results in a pain that is at times perfectly agonizing, and this very pain and inflammation produce an amount of irritation in the terminal nerve filaments going to supply these special parts, that, being transmitted to the nervous centre, which is the spinal cord, returns the impression of irritation to the muscular fibres of the sphincter; this produces renewed contraction that keeps up the trouble incessantly. Now if the sphincter muscle is divulsed until its fibres are for the time being put at rest, it breaks this nervous circuit by removing the irritation, and at the same time releases the pile tumors that were imprisoned in its remorseless grasp, thus allowing the free and easy return of blood from the inflamed tumors and assisting them in returning to their original quiescent state.

Again, we take a small fissure or ulcer within the grasp of the sphincter muscle, and every time the muscle is put upon the stretch by an evacuation of the bowel the pain that is produced is perfectly agonizing, for it tears open the bottom of the fissure or ulcer and exposes the terminal branches of the sensitive nerves to the irritating contact of the fæcal juices, and by the same nervous circuit as before mentioned the sphincter is thrown into spasmodic contraction and an agony of pain is kept up for hours. Now if the muscle is divulsed until the filaments are for the time being paralyzed, as stated before, the circuit is broken; the fissure or ulcer is given rest, and thus a chance to heal without being everlastingly held by the sphincter muscle.

There are no troubles that can be so relieved by rest as can the various diseases and injuries that are affected by this little sphincter ani muscle, and none of them can be relieved with any assurance of success until the fibres of this muscle are perfectly flaccid.

It is almost impossible to divulse the sphincter ani unless our patient is thoroughly under the influence of an anæsthetic, for the fibres of this muscle are among the very last in the entire anatomy to yield to the anæsthetic, and the pain produced by the divulsion is simply unbearable unless the anæsthetic is given.

The muscular fibres should never be torn, but by gentle kneading and stretching they should be rendered perfectly flaccid and for the time being paralyzed.

It is best first to introduce a bivalve or trivalve speculum, gently open the blades in various directions until the resistent force is partly overcome, and then use the fingers of each hand until the divulsion is completed. It should be remembered that the

[1] A paper read at a meeting of the Vanderburg Medical Society, March, 1898.

sphincter ani in women is much easier to divulse than is that in the male, and we should ever be on our guard not to carry the process so far as to endanger rupture of the muscle or its permanent paralyzation, for no more deplorable condition could be than this.

After the divulsion is completed and any operation in addition thereto that may be necessary for the relief of the particular trouble that may exist in each individual case has been performed, we should thoroughly sponge the anus and whatever part of the rectal mucous membrane that may be reached, with very hot sterilized water, and our patient should be put to bed and remain very quiet for at least six or eight hours.

There are but few physicians who realize the part played by the external sphincter muscle in the production of many cases of constipation. It is a proven fact that the sigmoid flexure is the receptacle or storehouse where the fæcal mass is retained from the time it leaves the colon until it is ready finally to be expelled by the act of defecation, the rectum being empty until just before the defecation act, when the fæcal mass enters the rectum from the sigmoid, and as soon as it does so there is produced the sensation of fulness, caused by the irritation of the fæcal mass upon the terminal nerve filaments of the internal pudic nerve; this irritation is transmitted to the spinal column and sent back to the muscular fibres of the external sphincter, which in its turn contracts and prevents the onward descent of the fæcal mass. Now if an opportunity is not presented for the final evacuation of the bowel, in a short time the fæcal mass is lifted back into the sigmoid to remain for another period. But if the opportunity for its evacuation is not presented, the mass becomes greater and its watery constituents are taken up into the system, leaving the hard and irritating mass to be packed down into the rectal pouch by the pressure of the abdominal contents and muscles, until its long contact with the mucous membrane produces an irritated or inflamed, or, may be, if not relieved in due time, ulcerated condition. The resulting irritation of the upper rectal nerves is carried by the same circuit as before mentioned to the sphincter ani, which continues its remorseless grasp until the will power has no control over it when the opportunity to evacuate the bowel does occur.

Now in such a condition as this, the more purgatives we give the worse the condition is rendered. If we anæsthetize our patient and thoroughly divulse the sphincter muscle, and clean out the rectal mass with large injections of hot water, we shall give the irritated, inflamed, or ulcerated (as the case may be) mucous membrane time to rest and heal, and thus relieve the constipation by divulsion of the sphincter ani.

Inoculation of Leprosy.—Dr. Osler, in a lecture recently delivered on leprosy (*Johns Hopkins Hospital Bulletin*), says that the possibility of successful inoculation must be recognized, though Hansen, the leading living expert on leprosy, declares that as yet all attempts at reproducing the disease by direct inoculation have been unsuccessful. He does not regard Arning's experiment on the Honolulu convict as satisfactory, since this man had leprous relatives. A number of observers, including some of the best students of the disease, have inoculated themselves, with negative results. The direct hereditary transmission must be excessively rare more so, indeed, than of tuberculosis. Since lepers have, as a rule, very few children, heredity can play only a very small part in the spread of the disease. Alvarez stated at the recent congress that he had never seen a newborn leper child; the youngest patient he had met with was three and a half years old.

MYRRH IN THE TREATMENT OF MALARIA.

By AARON JEFFERY, M.D.,

NEWPORT NEWS, VA.

THREE years ago Dr. William H. Ribble, of Wytheville, Va., told me he had a specific for chills and fever, which he had used for twenty years and which had in every case absolutely stopped the chills after forty doses. Before giving me the formula, which is a very simple one, he told me how he happened to use it.

One day, while riding to see a patient in Nelson County, Va. (which county in some sections is very malarious), he was joined on the road by an old man, who asked him where he was going. His reply was that he was on the way to see the most obstinate case of chills and fever he had ever come across, and one in which the largest doses of quinine seemed to have no effect. To cut a long story short, the old man gave him the following formula, which he used with the happiest result: Quinine, 40 gr.; pulverized myrrh, 20 gr.; and powdered licorice, 10 gr.; to be made into forty pills, one to be taken every two hours.

Shortly after Dr. Ribble told me of this, I moved to Newport News, Va., where I have had an abundant opportunity of trying the combination of quinine and myrrh, and always with the effect of cutting short the attacks.

I do not add the licorice, as it could have no possible effect, but order the myrrh and quinine to be put up dry in capsules. Of late I have been using two grains of quinine and one grain of myrrh in capsules and repeating the dose every three hours, instead of half the quantity every two hours. Very little is written in the text-books on the physiological actions of myrrh, but Binz, in his "Elements of Therapeutics," in speaking of myrrh, says: "From experiment we know that myrrh, even when given in doses of thirty minims of the tincture, increases the number of white blood corpuscles fourfold, and we know from counter-experiments that this result is not due to the alcohol." By some the white blood corpuscles are said to be the scavengers of the blood. If this be so, the plasmodium malariæ can be more easily eliminated, and the benefit derived by the addition of myrrh to the quinine in the treatment of malaria is explained.

Progress of Medical Science.

The Pupil Reflex in Infectious Diseases.—Dr. Corte draws the following conclusions: (1) In measles, scarlet fever, and ordinary small-pox the pupil reflex is normal; in the primary form of hemorrhagic small-pox it is weaker or absent. (2) In typhoid fever complicated with lung affection the pupil reacts slowly, whereas in infectious endocarditis the pupil reflex is absent. (3) In puerperal fever complicated with endocarditis or peritonitis the pupilreflex is wanting.—*Klin.-therap. Wochenschrift*, May, 1898.

Test for Sugar in Urine with Aniline Dyes.—Dr. Ludwig Bremer (*Centralblatt für innere Medecin*, 1898, No. 13) describes this test as follows: In two absolutely dry and clean test tubes put, in the one, ten cubic centimetres of normal urine; in the other, the same quantity of diabetic urine. Now drop in each a few grains of finely powdered gentian violet, in such a way that it comes in contact with the upper layer of urine at its centre, without touching the sides of the tube. The normal urine is either faintly tinged or not at all. In the diabetic urine there is, in a few seconds, a blue or blue-violet coloration of a larger or smaller urine layer at the top of the urine column.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 20, 1898.

WHO IS TO BLAME FOR THE NEGLECT OF THE SICK AND WOUNDED?

IT was not a pleasant task for the MEDICAL RECORD to arraign the medical department of the army for dereliction of duty in caring for the sick and wounded soldier. The obligation for taking such a course was forced upon us by the facts upon which a public scandal was founded. The necessity of criticising a department in the army in which every medical man throughout the country should have a becoming pride was offset by the chagrin that it had signally missed the opportunity of adding to a hitherto enviable reputation. What might have been and what was the case stand out in bold and striking contrast. The lessons to be learned from the Cuban campaign centre more around the neglect of the sick and wounded than any other features of the battlefield. This aspect is the more deplorable in that there are no evident reasons why the sick or wounded man should not have had the best of care. This was at least his due, and it was impliedly guaranteed him by the government. When the lamentable facts to the contrary are presented, it is extremely unfortunate for the surgeon-general that he should be held by the public so directly accountable. This will continue to be the case until an official investigation is made of all the departments of the army and the real blame for the many instances of inhuman treatment is properly placed on the guilty parties. Thus far we have been treated in the public prints with charges and countercharges, the only thing really admitted being the fact that the sick and wounded did not actually get the care they had a right to expect. It is quite evident in the present phase of the dispute that some attempt should be made to reconcile opposing statements and institute a thorough and searching investigation into all the known facts in this deplorable and reprehensible business. As we have said before, the surgeon-general of the army, for his own reputation and for the vindication of his corps, should demand an inquiry even from President McKinley himself. Until this is done the medical department will rest under suspicion of being accountable for all the disgrace and scandal. There is no one too high and too mighty to be brought before the bar of public opinion, when the gravity of the charges is duly considered. Whether the fault be due to the secretary of war, the general of the army in the field, the quartermaster-general, or the surgeon-general, the actual responsibility of wrongdoing should be definitely and fearlessly fixed by a properly constituted tribunal. If this is not done before the history of the present war is written, there will be on its otherwise brilliant page an ineffaceable blot over the doings of the medical department of the army.

We have in our last week's issue demanded of General Sternberg that whoever was responsible should be made known. If politics is at the base of this horror, then let the President himself start an investigation which will reveal the guilty, and by a prompt removal from office purge, so far as possible, the nation from complicity in such misdeeds. No office, however high, should shield the author of such criminal neglect. The people demand and the medical profession of the country demands that our good name and fame may be freed from this unjust implication.

THE ABDOMINAL INCISION.

SINCE it has become possible to be reasonably certain of getting primary union in our operative wounds, and to open with safety the various cavities of the body, more and more attention has been devoted to the technique of opening and closing these cavities. The abdominal cavity is perhaps the one which requires most attention from this point of view, both because it is so frequently the field of operative work, and because the patient's subsequent comfort and usefulness depend greatly upon the manner in which a wound in this region heals. Before the days of asepsis, the exact method of opening the abdomen was as a rule immaterial, and the operation was undertaken only in urgent cases. But now that laparotomy is such a common operation, more and more attention is being given to the character and location of the abdominal incision.

The linea alba is no longer the site of election for an incision which must be at or near the middle line, for surgeons are coming to believe that incision through one of the recti is followed by firmer union, partly on account of the greater thickness of the abdominal wall and partly on account of the contracting power of the muscle. An incision through the linea alba, when healed, protects against hernia only by the formation of cicatricial tissue, and the tendency of such tissue to stretch and atrophy is too well known to need comment. If the incision goes through muscular tissue in the direction of its fibres, healing takes place by the same process of cicatrization, but the new cicatricial tissue is supported by muscular tissue, which gives the abdominal wall much greater thickness and by its contractility is always tending to prevent stretching of the tender cicatrix. An accurate union of the peritoneal edges is of more importance in reducing the area to which the viscera may become adherent than in adding any real strength to the healed wound.

The importance of not dividing the nerves, even the small ones, is now generally recognized, for it has been found that atrophy of the abdominal mus-

cles is directly dependent upon interference with their nerve supply.

With such facts in mind, surgeons have been, during the past few years, devising various methods of opening the abdomen so as to divide as few fibres of any kind as possible, and these efforts have resulted in great improvement in technique when the operation involves opening the abdomen on either side low down. The so-called "intermuscular" method of McBurney, which might better be called "intramuscular," is one of the best of these methods, and enables the operator to avoid in great measure the division of fibres, either nervous or muscular. By it he can gain access to either iliac fossa, and with good retraction can do a surprising amount of operative work in these localities. The healing of the wound after this method of operating leaves the abdominal wall in a practically normal condition, and it seems impossible for a hernia to develop after it. In the iliac regions a transverse laparotomy has been done a large number of times, but we do not think that its performance has been accompanied by any great care to avoid division of fibres, and if the incision is made horizontally the nervous and muscular fibres are divided to as great an extent as in any other method. In cases in which more room is desired than can be got by the intramuscular method, it might be a good plan to divide the external oblique transversely, or nearly so, and to separate the fibres of the internal oblique and the transversalis, which, over the greater part of the iliac regions, are nearly parallel. By this plan we should get the benefit of the preservation of the nerve supply and muscle fibres of two of the muscles.

The method suggested by Kammerer for the removal of the appendix is also adapted to prevent subsequent hernia, and the interposition of the body of the rectus certainly gives us a powerful barrier against the development of such a condition. The wound is perhaps a little tortuous from surface to peritoneum, and the method necessitates rather strong retraction, a thing which the edges of fascia seem sometimes to resent.

In certain operations upon the gall bladder and its ducts we are often compelled to make large incisions, and frequently indeed to divide the rectus transversely. The healing of such a wound practically always leaves a weak abdominal wall, and it must be with a feeling of regret that the surgeon makes the transverse division of this muscle. An oblique incision near the border of the ribs gives a firmer wound than the T-shaped or L-shaped incision, since on one edge at least the subsequent scar has firm support. However, in this respect the gall-bladder region is not so important as are other regions of the abdomen, for here the viscera are comparatively solid and fixed, and the intra-abdominal pressure is not quite so great as in other parts. It is perhaps a trite, but none the less important, statement that success in preventing hernia by any method is directly proportionate to success in maintaining asepsis.

London and Paris have recently experienced a hot wave of unusual intensity, the mercury rising to 97° F. in Paris and nearly to that height in London.

A NEW BLOOD PARASITE AND THE FEVER ASSOCIATED WITH IT.

A PAPER by Dr. E. W. von Tunzelmann on the health of Chefoo, in the "Medical Reports of the Imperial Maritime Customs," No. 2, 1898, contains much valuable information in regard to malaria. Dr. von Tunzelmann, who had excellent opportunities for observation, made some careful and elaborate investigations into the bacteriology of malaria. The report is far too lengthy to transcribe in full, but many of the remarks contained therein are interesting in a high degree. Referring to case No. 4, Dr. von Tunzelmann says: "I have put this case last, though it was actually my first, because it was very complex, the non-malarial remittent fever, to which the fatal issue was due, being mixed with a malignant form of malarial quotidian As I wish to confine myself solely to the former disease, not to extend my paper to an excessive length I omit any detailed account of the symptoms. The patient was the commander of a coast steamer. He had been severely ill for six days; when I first saw him during this period his temperature had rarely been below 104° F. His blood was then found to contain in profusion the pigmented plasmodia of the malignant quotidian, 'summer-autumn' fever of the Italian observers, as well as a small number of those of tertian fever. The latter disappeared after the first day. The pigmented plasmodia disappeared speedily under the vigorous use of quinine by the mouth, hypodermically, and intravenous. As, however, these parasites were killed off, I observed from day to day increasing numbers of intracorpuscular bodies of a kind entirely unknown to me, and not mentioned in any works on malarial fevers with which I am acquainted. At the same time the blood, instead of becoming more and more watery, and therefore more readily diffusible between cover glasses, as is generally the case, got so sticky and mucilage-like in consistence that ultimately a drop just remained as such. I had therefore to change my technique in examining fresh blood, and to adopt the method of adding to the blood a drop of 0.75-per-cent. salt solution tinged with methyl violet, a liquid which in no wise affects the form of the elements. On the first occasion of so doing I had the good fortune to discover the adult forms of the parasites whose immature forms had been puzzling me for some time. Seeing that quinine was entirely without effect on these parasites, as had been clearly enough shown clinically already and as proved by experiment with the parasites under the microscope, I cast about for some drug which might prove lethal to them. Further good fortune led me to select methylene blue, and shortly after I began its use. I never saw again one of the above-referred-to extracorpuscular parasites alive in this patient's blood, though it always had dead ones in large numbers. Unhappily, it was too late for the methylene blue successfully to exert its beneficent influence; the patient was already beginning to fail, and, though a temporary effect was produced, it proved evanescent, death occurring three days after the discovery of the *materies morbi*."

This case is interesting because it shows that the

curative power of quinine in genuine malarial fever is due to its lethal action on the plasmodia, a fact which was proved both clinically and by actual ocular demonstration through the microscope. The case also shows the powerlessness of quinine to deal with the parasites associated with the complicating remittent fever.

THE "MEDICAL RECORD" AND THE SURGEON-GENERAL.

The action of the Medical Record in calling attention to the sufferings of our soldiers through lack of surgeons and medical supplies in the transports and on the field seems to have been misinterpreted by the surgeon-general of the army as a personal attack upon himself. At least, this is the inference to be drawn from the letters written by him and by Dr. Senn and others of his subordinates in answer to our criticisms. This misunderstanding is greatly to be deplored, for not only does it place our motives in a false light, but it tends to defeat the very object for which we are striving, namely, the fixing of the responsibility for the cruel neglect of the sick and wounded where it belongs, and, if the result of the investigation is such as we hope, the happy removal of the stigma from the army medical department. Through the fault of some one, or it may be of several, in authority, American soldiers suffered needless torture and death. The public naturally held the medical department of the army responsible for this, and if the blame could be fixed there, not only the surgeon-general and every one of his subordinates, but the entire medical profession of the country would be disgraced in the eyes of the world. Busied with the absorbing duties of his office, General Sternberg did not appear to realize the danger that menaced him and all his noble corps of surgeons, and in warning him of this danger we did but act the part of a faithful friend to him and a jealous defender of the honor of our guild. We believe that the surgeon-general is not personally accountable for the horrid neglect of our wounded heroes, but some one is, and Dr. Sternberg owes it to his professional brethren as well as to himself to fix the responsibility where it belongs. He can do so if he will, but unless he does so the blame will fall on him, and it is to save him from this injustice that we have urged and continue to urge him to court investigation.

MOSQUITOES AND MALARIA.

The account of the researches of Surgeon-Major Ross in the matter of an extra-anthropic host of the malarial plasmodium, read by Dr. Patrick Manson in the section on tropical diseases of the British Medical Association, and contained in our special report of the Edinburgh meeting, is one that cannot fail to interest our readers everywhere. Not only is the subject of malaria one of perennial concern to practitioners in many parts of the United States, but the method pursued by this patient worker, and that by which he achieved such brilliant results, is an example of what a truly scientific investigation should be. Dr. Ross did not content himself with the observation that there is no malaria in certain districts where mosquitoes do not bite—shrewd guesses based upon such coincidences had been made by Marchiafava and Manson years before Koch gravely announced the theory as his own—but he followed the plasmodium in all its evolutions and its travels through the body of the mosquito. It is true his studies were, for several reasons, made with the plasmodia pathogenic to birds, but the results may fairly be applied to man, and we have as a result the actual demonstration that, in whatever other ways malaria may enter the human body, one way at least is through the proboscides of the Culicidæ.

HOSPITAL JEALOUSIES.

If the reports which appear so frequently in the papers, of ill-feeling among the various hospital staffs in New York, are only half true, it is time that the authorities took the internes in hand. In one case a patient with fracture of the leg and forearm was to be moved from one hospital to another, and before the ambulance arrived the surgeons of the first hospital removed all the dressings and refused to help the ambulance surgeon from the second hospital to reapply them. In another case a woman with fracture of the patella was refused admission to a hospital because she was brought in an ambulance of another hospital. Such are the reported facts, and if they are correctly reported the young surgeons should be very forcibly reminded that their duty is to relieve suffering and not to vent their feelings of rivalry upon unfortunate patients who may be temporarily in their power.

News of the Week.

Behring's Unholy Attempt.—A firm of German manufacturers of diphtheria antitoxin has served notice on manufacturing chemists and others in this country not to make any more antitoxin, threatening them with a suit should they continue to manufacture it. Some of the houses making it in this country have announced that they will protect physicians using their serum, and doubtless all the other manufacturers will follow suit. Then we shall see whether a German doctor, whose title of discoverer of diphtheria antitoxin has never been unquestioned, can compel the United States to pay him tribute. The effrontery of the man is beyond belief.

Tetanus on Long Island.—Some alarm has been caused by newspaper statements that the soil at Montauk is infested with tetanus bacilli. Some years ago, when bony-fish manure was extensively used by the farmers, the eastern end of Long Island had an unenviable reputation as an endemic home of tetanus, and the bad name still sticks to it. Physicians practising there say, however, that tetanus is no longer met with—at least, that it occurs no more frequently on Long Island than in the country generally.

An Italian Medico-Legal Congress.—At the instance of the Italian Association of Legal Medicine, the first Italian national congress of forensic medicine will be held at Turin, during the first week in October, under the presidency of Prof. Cesare Lombroso. The secretary of the congress is Dr. Mario Carrara, of the medico-legal laboratory at the Royal University, Turin.

Weighty Arguments.—In the time of trial through which the surgeon-general of the army is now passing he may well pray to be delivered from his friends in the medical press. One of these alleges, apparently as an all-sufficient excuse for the neglect of the wounded, that the commander of the army in Cuba weighs three hundred and eighty pounds and has varicose veins! Another, whose own girth is notoriously out of proportion to his longitudinal measurement, seeks to divert criticism of the surgeon-general of the army by directing attention to the alleged fact that the surgeon-general of the Marine Hospital service is blessed with embonpoint!

The Losses in the War.—An estimate places the losses in the navy during the one hundred and fourteen days of war at 2 officers and 18 men killed, and 3 officers and 40 men wounded; in the army 23 officers and 231 men were killed, and 87 officers and 1,316 men wounded; the total loss was therefore 25 officers and 249 men killed, and 90 officers and 1,356 men wounded. The number of deaths in the army from disease is undoubtedly greater than that of deaths from Spanish bullets, but no figures have been made public upon which an estimate can be based.

The New York State Medical Association.—The regular annual meeting of the New York State Medical Association will be held at 64 Madison Avenue, New York City, on October 18, 19, and 20, 1898. The preliminary programme gives promise of a successful meeting.

An Island Hospital.—Mr. James A. Jones, of Deep River, has offered to the government the free use for hospital purposes of Hicks Island, near the military camp at Montauk Point, Long Island. The island is about thirty acres in area, and on it are several commodious buildings, wharves, boilers, engines, pumps, etc. Hicks Island is four miles west of Fort Pond Bay, where the camp is located.

Dr. John L. Feeny has been appointed by the board of health to the position of assistant sanitary superintendent for the borough of Richmond, to fill the vacancy caused by the death of Dr. George C. Hubbard. Dr. Feeny was for many years the health officer of Edgewater, and at the last election was the Democratic candidate for president of the borough.

Offer of the Health Board Declined.—In reply to an offer of the services of the medical men of the board of health to care for sick and wounded soldiers who may be brought to New York, the president of the health board has received a letter from Surgeon-General Sternberg, thanking him for the offer and saying that additional help is not needed now.

To Dr. S. A. Knopf, of New York City, has been awarded the Alvarenga prize of the College of Physicians of Philadelphia for 1898, for his essay entitled "Modern Prophylaxis of Pulmonary Tuberculosis, and its Treatment in Special Institutions at Home."

Seaboard Medical Association.—The second semi-annual session of this society, composed of practitioners in Eastern Virginia and North Carolina, was held at Virginia Beach, Va., July 14th and 15th. The election of officers resulted in the choice of the following: *President*, E. F. Corbell, Sunbury, N. C.; *Vice-Presidents*, Charles T. Parrish, Portsmouth, Va., and T. N. White, Belvide, N. C.; *Secretary*, John C. Rodman, Washington, N. C. The next meeting will be held in Wilson, N. C., in January, 1899.

The Salaries of German Professors.—A correspondent of the *British Medical Journal* says that the Prussian minister of finance has devised a scheme whereby the government may save the salaries it now pays to the medical professors in the State universities. He has issued a confidential circular asking for co-operation in a sliding-scale scheme of self-taxation, a scheme which would reduce the State salary in proportion to the annual income (above a certain sum) accruing from private practice. This extraordinary proposal, reduced to plain terms, means that a professor earning from $5,000 a year in private practice would enjoy the enviable distinction of serving the State gratis.

The Yellow-Fever Visitation at McHenry.—The limitation and then stamping out by the prompt action of the Marine Hospital service and the Mississippi State board of health of yellow fever at McHenry, Miss., are a cause of great gratification. The total number of cases was twenty-four. The last patient was discharged July 8th, since which time there have been no other cases under treatment and no suspicious ones reported. This is probably the first early outbreak to be so successfully arrested. The Marine Hospital service and the Mississippi board deserve congratulation, both for the achievement itself and the valuable and encouraging lesson it teaches.—*New Orleans Medical and Surgical Journal.*

Safety in Match Making.—The Belgian government has voted a sum equivalent to $10,000 (open to competitors of all nations) to any one who can compound a marketable match paste without the aid of yellow phosphorus. The paste must not be liable to explosion in manufacture, and must not contain any substance dangerous to the health of the workpeople. Application for conditions should be made to M. Woeste, Rue Latérale 2, Brussels.

The Hebrew Orphan Asylum in this city has been emptied, its inmates having been taken to the seashore, in order to put an end to an epidemic of dysentery which threatened to assume dangerous proportions. The disease appeared about three weeks ago, and 150 of the 865 children were attacked, 5 dying. The cause of the outbreak seems to be undetermined, but a thorough examination of the waterpipes and sewer connections will be made.

The Ambulance Ship "Solace."—Surgeon-General Van Reypen, of the navy, has recommended the retention of the *Solace* as a permanent ambulance ship in the navy, and it is not improbable that another may be added, possibly for service in the Asiatic fleet.

The Fifth International Congress on Drinking-Water and Mineral Waters is to be held at Liége, from September 25th to October 3d. The secretary is Dr. Jorissene, 130 Boulevard de la Sauvenière, Liége, Belgium.

Some Michigan Surgeons.—Maj. Charles B. Nancrede, brigade surgeon, is home from Cuba on a furlough. He was detailed to accompany wounded soldiers from the front to the general hospital at Norfolk, Va., and will spend thirty days recuperating in Michigan. The doctor has recently been winning laurels from the forum as well as from the field. At the late commencement exercises of Jefferson Medical College, the authorities of that institution conferred the degree of LL.D. on him. Maj. Victor C. Vaughan, who succeeded Dr. Nancrede as regimental surgeon, was recently stricken with yellow fever in Cuba and removed to the isolation hospital. He has been granted leave of absence, and is now *en route* for home. Dr. H. ... Thomason, of Albion, Mich., will immediately report before Santiago to accept the surgeoncy of the thirty-third.—*The Physician and Surgeon.*

The Practice of Medicine in the Klondike.—A correspondent informs us regarding the condition of medical practice at Dawson City and vicinity, that although there are only eight or ten registered practitioners in the Yukon Valley, there are not less than two hundred practising in Dawson City without registration according to the laws of the Northwest Territory.

The Bubonic Plague is again epidemic in Bombay. One hundred and three deaths were officially reported during the week ending August 13th.

The American Microscopical Society.—The twenty-first annual meeting of this society will be held in Syracuse, N. Y., August 30, 31, and September 1, 1898. The sessions will be held in the new building of the Syracuse University Medical College, where every facility of rooms and apparatus will be put at the disposal of the society. The meetings will begin at 10 A.M. and at 2 P.M. At the opening session, Tuesday, August 30th, the addresses of welcome will be followed by the reading and discussion of papers. On the evening of Tuesday the annual address by the acting president, Prof. V. A. Moore, of Cornell University, will be delivered, after which members will meet socially in the rooms of the Citizens' Club. Wednesday afternoon there will be given demonstrations of the projection microscope and of laboratory apparatus. In the evening of Wednesday will occur the *soirée*. Thursday afternoon the society will be shown much of interest in the New York State Institution for Feeble-minded Children. Owing to the State fair, held in Syracuse from August 29th to September 3d, a round-trip ticket from any station in New York State may be purchased for half the usual rate, and fifty cents (which entitles the holder to one visit at the fair). All interested persons are invited to be present, join the society, and read and discuss papers or demonstrate apparatus and methods. For particulars as to membership, etc., letters may be addressed to Prof. S. H. Gage, Ithaca, N. Y., or Dr. A. C. Mercer, Syracuse, N. Y.

The Medico-Psychological Society of Quebec was recently established by a number of the resident physicians in the hospitals for the insane in the province of Quebec. At the first meeting twenty members were present, and elected the following officers: *President*, Arthur Vallée, of the Quebec Insane Asylum; *Vice-President*, T. J. W. Burgess, of the Protestant Hospital for Insane; *Secretary*, E. P. Chagnon, of Longue Pointe.

A Typhoid-Fever Inquiry.—It is announced from Washington that Surgeon-General Sternberg has decided to appoint a commission to investigate the cause of typhoid fever in the army camps, and report upon a method for the prevention of camp epidemics of the disease. The commission will consist of Major Walter Read, United States army, Major Victor Vaughan, division surgeon of volunteers, and Major Edward O. Shakespeare, brigade surgeon, United States volunteers.

Yellow Fever.—Some, apparently needless, alarm was caused recently by the announcement of the discovery of a case of yellow fever at Franklin, La. Fortunately the case, if it was of yellow fever, was an isolated one and the Louisiana health authorities say that the town is now in a perfectly healthy condition. Three cases of the disease were reported on Wednesday from the marine barracks at Key West. It is not believed that the fever will spread, as energetic measures have been taken by the Marine Hospital, State, and naval medical officers to limit it. Three men ill with yellow fever were on the transports bringing the Rough Riders and members of the seventy-first regiment of New York from Santiago to Camp Wikoff at Montauk Point, and there were many more suffering with a suspicious fever.

The Hospital Ship "Missouri" will, it is reported, be sent to Manila as soon as it is fitted up, the cessation of hostilities taking away the necessity of more than one army hospital ship in the West Indies. The *Missouri* has accommodations for four hundred patients, forty-five nurses, and ten surgeons. She is not so handsomely decorated as the other hospital ship, but has some practical advantages over the *Relief* in other respects.

The Marine Hospital Service and National Quarantine.—The advantage of having the quarantine of the country under national control, so that the rules may be uniform and prompt, and vigorous measures enforced at all points, is being constantly illustrated during the present war. The fact that the Marine Hospital service is a department of the general government has enabled Surgeon-General Wyman to cooperate readily with the army and navy departments in his efforts to prevent the invasion of yellow fever from Cuba.—*The Medical News.*

The Camp at Chickamauga.—Surgeon-General Sternberg has, it is said, informed the secretary of war that he does not favor the abandonment of the military camp at Chickamauga. He says that the illness among the troops is, in the opinion of surgeons of the medical corps, not due to any defects in the geographical situation or in the water supply, but is due almost entirely to the careless methods of living of the soldiers. The men generally sleep on the ground instead of on cots or in hammocks, and they are not careful to observe the directions of the medical department in regard to drinking boiled water and the avoidance of improper articles of food. It is believed that if the troops are moved to Lexington or Nashville the sickness will be as bad, if not worse, especially if the men are sent to either of these places on foot, as was originally proposed.

Ice-Cream Poisoning.—Several deaths and many cases of serious illness in children who have indulged in "hokey-pokey" have occurred in London this season. The papers, both lay and medical, are calling for the suppression of the itinerant ice-cream vender.

A School for the Study of Tropical Diseases is about to be established in London. With this school, the creation of a section on tropical diseases of the British Medical Association, and the prominent publication of a journal of tropical pathology, the British medical men who have had such a wide experience in tropical medicine in the colonies seem at last to be awakening to the responsibility which rests upon them to instruct their successors in this most necessary branch of medicine.

A New Way.—A correspondent of the *Canadian Journal of Medicine and Surgery* writes that he was astounded beyond measure the other day to come across the following advertisement pasted up alongside of a telephone in one of Toronto's business houses, printed in blue and red ink: "In case of any accident in this establishment, telephone at once for Dr. ——, No. — —— Street." The astounded correspondent remarks that "surely such cannot be professional."

The Heart, the Bicycle, and the Cigarette. — In an article in the *Medical Standard*, detailing the results of the physical examination of 9,901 officers and men of the Illinois national guard, Lieut.-Col. Charles Adams, speaking of the heart, says: "In the preliminary examinations of recruits made by the medical officers of the different regiments before leaving their home stations, many cases of 'bicycle heart' were discovered and not allowed to enlist. These were characterized by hypertrophy and dislocation of apex beat with irregular or rapid beat. In view of the sensational statement in the lay press that hundreds of young men had been refused enlistment in the United States volunteers at Springfield for 'tobacco heart' caused by cigarette smoking, it is worth noting that no case of the kind is recorded in the examination at Springfield, and we have no knowledge of any rejections for that cause in the preliminary examinations at Chicago or elsewhere in the State. We make this statement on behalf of the truth, not of the cigarette."

An Old but not Wholly Satisfactory Explanation of the Occurrence of Typhoid Fever.—Dr. J. Fred. Clarke, a surgeon of volunteers, writes to the *Philadelphia Medical Journal* from Camp Cuba Libre, in Jacksonville: "We have good water, hot sun, heavy rains and dews, the intemperance usual in armies, and some necessary work. The result is much typhoid fever and more of the shorter continued malarial fevers. . . . Whether this typhoid fever was brought here from State camps is a question often discussed. I find a prevailing opinion among the regular army surgeons that the typhoid bacillus is but a modified form of the bacillus coli communis, frequently so changed in its behavior by the conditions of army life."

Chicago as a Health Resort.—During July there were 1,938 deaths in Chicago from all causes, which makes the low annual death rate of 14.8 per 1,000 inhabitants, assuming that the estimate of population upon which these figures are based is correct. According to *The Tribune* of that city, the cool lake breeze has a direct effect upon the death rate, as is shown both by the figures of last year and by the figures of hot and cool periods of the July just past. During the first fifteen days of the month the temperature was four degrees lower than the twenty-seven years' average, while during the last sixteen days of the month the mean temperature was seven degrees higher than the average. The daily deaths were thirty per cent. more during the hot period than during the cool period. But the steady decrease in the city's death rate from year to year is undoubtedly due to the increasing cleanliness of the streets and alleys, and the improved sanitary conditions.

The Medical Society of Virginia.—The twenty-ninth annual session of this society will be held at Virginia Beach, August 30 and 31, and September 1, 1898. The president of the society is Dr. Lewis E. Harvie, of Danville, and the secretary Dr. Landon B. Edwards, of Richmond.

The British Society for the Prevention of Cruelty to Children reports that during the year 1897, 25,170 complaints were received by the society, leading to action in 18,779 cases, to prosecutions in 2,519, and that 96.55 per cent. of such prosecutions were successful. The number of children whose interests were involved in all these cases was 68,008.

The Hahnemann Monument.—Every visitor to the American Medical Association remembers the difficulties encountered by the Rush monument fund committee in its work. The statement has been made at these meetings that the homœopathic physicians of the country had already raised the amount necessary to erect a much finer monument to Hahnemann than the one contemplated for Benjamin Rush. Now comes the statement, says the *Columbus Medical Journal*, that the monument is finished, but that it is not in place and will not be until the homœopathic profession comes forward with the amount necessary to pay for it. What the delinquency amounts to is not stated, further than that "three dollars from each homœopathic physician in America would liquidate all claims and place the monument in Washington."

Reviews and Notices.

THE METHODIST EPISCOPAL HOSPITAL REPORTS. Volume I., 1887–1897. Edited by L. S. PILCHER, M.D., New York, and G. R. BUTLER, M.D., New York. Published by the Hospital. 1898.

THIS report consists of an interesting *résumé* of ten years' work at a large hospital, with papers on various topics by different members of the staff of the institution. The whole book is characterized by the excellence of its plates and the good general style of its make-up. The gynæcological cases reported by Dr. Pilcher are such as occur in the regular routine of any large service and do not require special attention in a review, although they will afford useful statistical information for the specialist in this department of surgery. Dr. Fowler's article on appendicitis is illustrated by several remarkably good colored plates of the appendix, showing various forms of inflammation which may affect that organ. The experience of the surgeons at this hospital with this disease indicates that it has become much more prevalent in ten years, or else that many cases formerly went unrecognized and were not sent to the hospital for operation. The latter explanation must be the correct one, and it is a favorable indication that knowledge of this disease is becoming widely disseminated, so that patients reach the operator in time without being treated a while beforehand for "acute indigestion." The relation of age and sex in the cases seems to be about the same as elsewhere.

Twenty-seven operations upon fractured patellæ are mentioned, and we regret that there are not given more particulars as to the ultimate result in respect to joint motility. The four cases of hip-joint exarticulation for sarcoma behaved in the way with which we are unfortunately familiar—one patient was living six months after operation, one died of shock, and two died very soon of metatasis or recurrence.

An analytical report of the fatal cases of typhoid fever will repay perusal, as will the paper on thermic fever and heat prostration. In the latter condition we may note that alcoholic stimulation was not used after the first day, but the other heart stimulants were found useful. This seems to accord with the experience of those who have seen the most cases of the disease. The obstetrical cases reported are such as are usually met with in hospital service, and require no special comment.

DISCOS DE MARFIL DESCALCIFICADO PARA LAS ANASTÓMOSIS Y REUNIÓN DEL INTESTINO EXTREMO CON EXTREMO. DR. R. MARTIN GIL, Medico-Director del Hospital Noble de Málaga. Pp. 7.

THE suggestion embodied in this pamphlet for the formation of an end-to-end anastomosis by the use of decalcified ivory plates held together by elastic bands may in some cases give us a convenient method for the accomplishment of our object. It seems, however, that this surgical procedure should be directed toward making the anastomosis as simple as possible, even if we should take a little more time in doing it. Many cases requiring the operation of anastomosis are seen far from places where we can get ivory plates or Murphy buttons, and with this in mind it appears to be better to direct our efforts toward making our suture methods as rapid, safe, and accurate as possible without the use of any kind of apparatus. Dr. Gil's discs are surgical novelties, but we cannot see that they present advantages over methods and apparatus which have already been suggested.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume XIV. "Infectious Diseases." New York: William Wood and Company.

THIS second volume upon the infectious diseases includes, besides the exanthemata, glandular fever, pertussis, cholera infantum and true cholera, dengue, beriberi, miliary fever, and Malta fever. The last-mentioned febrile affection will probably be more familiar to many readers by the name Mediterranean fever. Dr. David Bruce, of Pietermaritzburg, South Africa, surgeon-major of the British army and formerly professor at the Netley Army Medical School, has written a most entertaining and instructive chapter describing this fever and the conditions on which it depends. Scarlatina has been ably dealt with in one hundred and fourteen pages by Forchheimer, who also has written on rubella. Dawson Williams, of London, devotes sixty pages to measles, and covers the ground well. Whooping-cough has received attention at the hands of the late regretted Joseph O'Dwyer and of Nathaniel Read Norton. Koplik's bacillus is described, and, while doubt is entertained as to its identity, it is stated that the weight of evidence points in favor of its being the pathogenic germ of the disease. A short chapter on glandular fever by Dawson Williams gives credit to West, of Ohio, for an excellent description of the most widespread epidemic yet recorded. Cholera infantum well fell to the lot of A. Jacobi, and Theo. Rumpf, of Hamburg, it would seem, was wisely chosen to give an account of cholera from a modern standpoint. He does it in one hundred and fifty well-written pages. Dengue is briefly considered by Sir Joseph Fayrer, of London, and beriberi by De Azevedo Sodré, of Rio de Janeiro. The editor did well to select a French author to write upon miliary fever, and Professor Netter, of Paris, has given an entertaining description of this peculiar affection. The volume compares well with former issues in points of interest and completeness.

THE INTERNATIONAL MEDICAL ANNUAL AND PRACTITIONERS' INDEX. A Work of Reference for Medical Practitioners. Sixteenth Year. New York: E. B. Treat & Co. 1898.

THIS is a review of the medical literature of the year, having special reference to new remedies and newer methods of treatment. A feature of the present issue is the partial work of Shattuck on pathogenic bacteria, which will be completed in the next number. The part already given contains many interesting and instructive plates. This year's "Annual" is freely illustrated and contains a fund of general information.

DIE KRANKHEITEN DES MAGENS. Ein Lehrbuch für Aerzte und Studirende. Von DR. MAX EINHORN. Berlin: S. Karger. 1898.

THIS book is practically a German translation of the work by the same author recently published by Wm. Wood & Co. Those familiar with the English edition know what a valuable contribution to the literature of gastric diseases this has been, and it is safe to say that the work will be sufficiently appreciated abroad to warrant its having been translated and published in a foreign language. There are fifty-two illustrations, all of which clearly explain themselves. Though many similar works by German authors have appeared within recent times, still this one, on account of its clearness and practical import, cannot fail to find favor with even the scientific Germans.

YELLOW FEVER IN THE WEST INDIES. By IZETT ANDERSON, M.D. London: H. K. Lewis. 1898.

AFTER a residence of thirty-four years in the West Indies, the author has given the results of his practical experience during that time, in both the epidemic and sporadic forms of yellow fever. The book does not deal with theories and discussions, but presents a *résumé* of the extensive records kept by the writer, which were referred to in the RECORD'S editorial columns of May 14th.

FESTSCHRIFT GEWIDMET FILIPP JOSEF PICK aus Anlass der Vollendung seiner 25jahrigen Thatigkeit als Professor und Vorstand der k.k. dermatologischen Klinik in Prag. Redigirt von GEHEIMRATH PROF. A. NEISSER in Breslau. Wien und Leipzig: Wilhelm Braumüller. 1898.

THIS handsome souvenir of Professor Pick's twenty-fifth anniversary is given out as volumes xliii. and xliv. of the *Archiv für Dermatologie und Syphilis*. It has been prepared as a mark of honor, esteem, and kindly recollection by his colleagues and pupils. Each part contains somewhat over five hundred pages, the first having twenty-five plates, the second fifteen, showing rare and interesting states of special importance to the dermatologist. The "Festschrift" reflects much credit upon the many who have contributed to its existence and attractiveness, and the subject of the attention should feel gratified at this mark of the esteem in which he is held by his colleagues of all countries.

DOCTOR AND PATIENT. Hints to Both. By DR. ROBERT GERSUNY. Translated, with the permission of the Author, by A. S. LEVETUS, with a Preface by D. J. LEECH,

M.D., F.R.C.P., etc. Bristol: John Wright & Co. 1898.

To the young practitioner in particular, and to many of the older ones, this little book will commend itself, on account of its wealth of practical information and suggestion as to that attitude of physician and patient which will be conducive to the greatest mutual benefit. Those who read this little dissertation must agree with the writer of the preface, who says: "One cannot rise from the perusal of Dr. Gersuny's book without feeling better for the wise counsel he gives, and without having received an incentive to do that which is right and maintain at its highest point the honorable position of the profession."

Diseases of the Stomach. By William W. Van Valzah, A.M., M.D., and J. Douglas Nisbet, A.M., M.D. Illustrated. Philadelphia: W. B. Saunders. 1898.

Van Valzah and Nisbet present their own experience and the views of the leading authorities in this clearly and concisely written book on "Diseases of the Stomach." With regard to the nomenclature, the terms "adenohypersthenia" for "hyperchlorhydria," and "adenasthenia" for "hypochlorhydria" do not seem to us a needful innovation. The chapter on diet is complete and thorough. The last section, "The Vicious Circles of the Stomach," comprising two chapters ("Other Organs in Diseases of the Stomach" and "The Secondary Diseases of the Stomach"), is excellent and most original. As a good instance of the clear way in which the present work is written we may mention particularly the description of "vertigo a stomacho læso." As a whole we can recommend this book highly.

Transactions of the Vermont State Medical Society, 1897. Published by the Society.

While for the most part society reports contain a mass of dry and uninteresting facts, still this little volume presents much that will prove of both practical and theoretical import. One has but to read the exhaustive and excellent article on "The Modern Management of Diphtheria and Croup Cases," by Dr. A. Caillé, to feel fully repaid for having given this report a place in his library. Numerous other articles of a medical and surgical nature add to the value of the book.

Transactions of the New York State Medical Association. For the year 1897. Volume XIV. Edited for the Association by E. D. Ferguson, M.D., of Rensselaer County. New York: Published by the Association.

An interesting report, not only on account of the number of instructive articles, but because of the excellent arrangement of the entire subject matter, especially the chapter on the "Materia Medica, Pharmacy, and Therapeutics of the Year Ending October 1, 1897." The latter presents in alphabetical order the newer drugs of the past year, with a concise description of their uses and appropriate formulas for the same. Among other things there are memoirs of the late Dr. J. Lewis Smith and Dr. William T. Lusk, memoirs which should prove of more than passing interest to every medical man. The *tout ensemble* of this volume leaves nothing to be desired; the print is clear, the binding neat and attractive.

Recent Materia Medica and Drugs Occasionaly Prescribed. Notes on their Origin and Therapeutics. Fifth Edition. By F. Harwood Lescher, F.C.S. London: J. & A. Churchill. 1897.

Advance information is often of great value to the physician. This work of about two hundred pages, compiled from current literature for the most part, brings together those drugs and preparations which are likely to find a place in medicine, and tells what they are, so far as this is possible. The present edition has been revised up to 1897. Too many proprietary articles are noticed.

Die Hyperplasie der Rachentonsille und die adenoiden Vegetationen des Nasenrachenraumes. Von Dr. Gustav Abeles, Prakt. Arzt in Wien. Druck und Verlag von C. G. Naumann.

In the space of some one hundred pages the author fully describes the symptoms, diagnosis, complications, and methods of operation on the pharyngeal tonsil of Luschka and the adenoid vegetations at the vault of the pharynx. This is all given from the standpoint of the general practitioner rather than of the specialist, and should therefore prove of value to the greater number of physicians. All in all, this little work offers very interesting and instructive reading-matter.

The Year-Book of Treatment for 1898. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia and New York: Lea Brothers & Co.

This is the fourteenth annual appearance of an attractive retrospect. When it is remembered that such editors as Reginald Harrison, Edmund Owen, Alfred Cooper, Ernest Lane, Handfield-Jones, Malcolm Morris, Willoughby, and others supervise the various departments, one may be sure of results such as have made and kept this year-book popular.

The Purification of Public Water Supplies. By John W. Hill, Consulting Engineer, Member American Society of Civil Engineers, etc. New York: D. Van Nostrand Company. 1898.

The author has already put himself before the scientific public by his lectures and writings on water and the ways of keeping it pure for public supply. The present volume embodies the views expressed elsewhere at various times. All having the public health in charge would do well to make themselves familiar with the results of research and experience here embodied. The portions devoted to filters and filtration might well be read by those who will be responsible for the health of our army in the immediate future.

Notes on Military Hygiene for Officers of the Line. A Syllabus of Lectures formerly Delivered at the United States Infantry and Cavalry School. By Alfred A. Woodhull, LL.D. Princ., Lieutenant-Colonel, Medical Department, United States Army. New Edition, Revised and Augmented. First Thousand. New York: John Wiley & Sons. London: Chapman & Hall, Ltd. 1898.

This is a very timely little manual and one which contains much useful information to military men. The one hundred and seventy-one pages neatly bound make a book of convenient pocket size, which should prove acceptable to officers of the line or to the private.

An American Text-Book of Genito-Urinary Diseases, Syphilis, and Diseases of the Skin. By L. Bolton Bangs, M.D., Consulting Surgeon to St. Luke's Hospital and to the City Hospital, New York, and to the Methodist Episcopal Hospital, Brooklyn; Visiting Genito-Urinary Surgeon to St. Mark's Hospital, New York; late Professor of Genito-Urinary and Venereal Diseases, New York Post-Graduate Medical School and Hospital; and W. A. Hardaway, A.M., M.D., Professor of Diseases of the Skin and Syphilis, in the Missouri Medical College, St. Louis; Physician for Diseases of the Skin to the Martha Parsons Hospital for Children and to St. John's Hospital, St. Louis. Illustrated with 300 Engravings and 20 Full-Page Colored Plates. Philadelphia: W. B. Saunders. 1898.

In the compilation of this work the editors have exhibited care and painstaking discrimination. The choice of authors has been in the main good. Various articles are written in a clear, pleasing style. The work is progressive, concise, and yet quite complete.

The first half of the book deals with diseases of the genito-urinary tract, both inflammatory and surgical, and opens, very properly, with an introductory chapter on urinary analysis. Somewhat surprising to the reader, in a work of this order, is the amount of space devoted to surgical conditions and their treatment; it is commendable, however, in that the most recent surgical procedures have been incorporated.

The section on syphilis is subdivided according to the regional manifestations of the disease, a classification that might properly be spoken of as specialistic syphilology. The remainder of the book, devoted to dermatology, contains all the information regarding diseases of the skin required of the medical student or necessary for the general practitioner. In its entirety the work is a handy reference volume, and one that may well find a place in any medical library.

The Surgical Complications of Typhoid Fever. By William W. Keen, M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Vice-President of the College of Physicians of Philadelphia, etc. Based upon Tables of Seventeen Hundred Cases Compiled by the Author and by Thompson S. Westcott, M.D., Instructor in Diseases of Children, University of Pennsylvania; Visiting Physician to the Methodist Episcopal Hospital, Philadelphia. With a Chapter on the Ocular Complications of Typhoid Fever, by George E. de Schweinitz, A.M., M.D., Professor of Ophthalmology, Jefferson Medical College; Professor of Diseases of the Eye, Philadelphia Polyclinic, etc.; and as an Appendix the Toner Lecture, No. V. Philadelphia: W. B. Saunders. 1898.

The title page tells the whole story and should be sufficient guarantee that the twenty-one chapters will present a fund of information of an important kind. The list of illustrations includes four plates and nine figures. There are three hundred and eighty pages and an index. The Toner lecture, on the surgical complications and sequels of the continued fevers, was delivered by Dr. Keen in 1876. It makes good reading to-day.

Hospital Formulary of the Department of Public Charities of the City of New York. Fifth Edition, Revised. 1898.

The board and chemist Rice are to be congratulated upon the output of so attractive a list of formulæ, to say nothing of the information under "Miscellaneous Subjects."

Diabetes Mellitus and its Treatment. By R. T. Williamson, M.D., M.R.C.P.; Medical Registrar, Manchester Royal Infirmary; Hon. Med. Officer, Pendleton Dispensary, Salford Royal Hospital; Assistant to the Professor of Medicine, Owens College, Manchester. Edinburgh and London: Young J. Pentland. 1898.

The name of the author has come of late to be familiar to American readers by reason of the test for diabetic blood, devised by him and known by his name. As a result of some ten years' experience in the disease, the present work has been produced. The subject has been entered into at much greater length than one could look for in a system of medicine or a text-book. There are four hundred and seventeen pages, including the indexes. There are eighteen illustrations, two of which are colored. There are fourteen chapters, one of which is on the pathological anatomy, but the anatomical lesions are briefly referred to in each chapter besides. Experimental diabetes and glycosuria receive considerable attention and the various causes of the latter are considered at some length. The work is well and carefully written, and the writings of such well-known authors as Seegen, Ebstein, von Noorden, Pavy, Saundby, and many others have been freely quoted. The publishers have produced an attractive volume.

Excretory Irritation and the Effect of Certain Internal Remedies on the Skin. By David Walsh, M.D. Edin.; Physician, Western Skin Hospital; Clinical Assistant, Blackfriars Skin Hospital, etc. New York: William Wood and Company. 1898.

The substance of this work represents a graduation thesis. By excretory irritation the author intends to have understood irritation of either epithelial or nerve cells.

In a brief monograph of sixty-five pages are discussed the relation of inflammations to the excretory functions of the body.

Naturally skin diseases and the effects of drugs upon the excretory apparatus enter largely into the question as it has been considered by the author. Dermatologists will find many points of interest in this little work, and it will also be of interest to scientific men generally.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Volume III. January, 1898. Edited by Andrew J. McCosh, M.D., and Walter B. James, M.D. New York: Trow Directory Printing and Bookbinding Company. 1898.

The embodiment in a periodical report of the work done in a large hospital cannot fail, if well done, to contain much that is useful. In this report of the Presbyterian Hospital we have a series of articles by men connected with the institution, written from material drawn from hospital sources. Dr. Thacher has contributed a careful paper upon "Hydrochloric Determinations," and a paper by Dr. James, on the "Bacteriology of the Blood in Disease," contains much of value to those interested in this special branch. There is a long series of examinations in the most important diseases, rheumatism, typhoid fever, tuberculosis, and meningitis among others. A subject of more local interest is the one of malarial fevers in the city of New York, and as the disease seems in this city to present very often unusual and irregular manifestations, careful compilation of observations upon it must prove useful. We have in this report an interesting paper upon the subject of intermuscular operations for appendicitis, written by Dr. Briddon. Many suppurative cases were operated upon by this method, which, when it was first suggested, was believed to be suitable only to non-purulent instances of the disease. However, the success of the method seems to have been marked in many of these cases, and it will be interesting to note whether any of these patients develop hernia, and whether in suppurative cases, when it is possible to use this method, there is any less tendency to this condition than by other operative methods. Forty-one hysterectomies and fifteen abscesses of the brain make a great deal of material, but these are the cases reported and described in this volume. Many of the other papers are interesting, and the book contains much material which will prove useful from a statistical point of view.

Inflammation of the Bladder and Urinary Fever. By C. Mansell Moullin, M.D. Oxon., F.R.C.S., etc. Philadelphia: P. Blakiston, Son & Co. 1898.

The author has embodied in this volume his own ideas and experiences. The first sixty or seventy pages are devoted to a discussion of the symptomatology and etiology of cystitis of various kinds, from simple cystitis to suppurative cystitis, with the presence of various forms of micro-organisms. These pages present the subject in a clear and comprehensive manner, and the author has given us a satisfactory classification of the various conditions he is discussing, upon which he seems to have some very positive ideas. The pages devoted to urinary fever give a very clear description of the various conditions grouped under this general head, but we question the advisability of using such a term as "urinary" fever. The manifestations are entirely of a septic nature, due to the entrance of various organisms into the body and to products of their metabolism, and the urine is merely a nutrient medium for the growth of these organisms. The only thing to be said in favor of the term is that it is convenient. The author's four forms of this condition cannot be very well marked off from each other, except the first one, which is undoubtedly distinct, and may have some nervous element in its causation. The bacteriology of cystitis is gone into in an interesting way, and considerable prominence is justly given to the bacterium coli. The treatment of the various forms of cystitis is presented satisfactorily, but we think that there is nothing in this part of the book requiring extended comment. The treatment of cystitis can be summed up in free drainage and asepsis, with all that those terms imply.

Diseases of Women. A Practical Text-Book. By H. N. Lewers, M.D. Philadelphia: P. Blakiston, Son & Co. 1898.

This is a useful handbook which will doubtless be valuable to the student of gynæcology. The chapters are well arranged and the classifications such as will appeal to the student class of readers. The book has been considerably revised and the chapter on extra-uterine gestation is improved in its re-written form. The style of composition is perhaps a little more colloquial than is desirable in a scientific treatise, especially in the clinical histories, some of which savor rather too much of the red-flannel and sage-tea days of gynæcology in their choice of words.

The illustrations all through the book are satisfactory and there is a good index. The author clings to the mongrel "ovariotomy" rather than use the more correct "oöphorectomy." But medical men will apparently never be purists in the matter of language.

Clinical Report of the Rotunda Hospitals. For One Year, November 1, 1896, to October 31, 1897. By R. Dancer Purefoy. Dublin. 1898.

A short and running account of the interesting cases of the year is here presented. The report could be read by the obstetrician to advantage, and has the merit of being concise.

A Manual of Instruction in the Principles of Prompt Aid to the Injured, Including a Chapter on Hygiene and the Drill Regulations of the Hospital Corps, U.S.A. Designed for Military and Civil Use. By Alvah H. Doty, M.D., Health Officer of the Port of New York. Second Edition. New York: D. Appleton and Company. 1898.

This is a very excellent short manual for those who are liable to come in contact with large bodies of people exposed to accidental risks. The principles of "What to do" and "How to do it" are here well presented. At the present time, when our soldiers are exposed to the dangers of a southern climate and a strange wilderness, the facts here presented cannot fail to be of service to them, and when the high average of intelligence of our men is considered we might well wish the book a wide reading.

Electro-Physiology. By W. Biedermann, Professor of Physiology in Jena. Translated by Frances A. Welby. Volume II. London and New York: Macmillan and Company. 1898.

To those who have had the opportunity to see the first volume of Biedermann's "Electro-Physiology" this second volume will prove of added value. In it the same scholarly and minute survey of the fundamental electro-physiological facts is maintained. For those to whom the work is new, the second volume stands out as a separate and complete treatise on biological electrical phenomena. Its six chapters consider electromotive action in vegetable cells, structure and organization of nerve, conductivity and excitability of nerve, electrical excitation of nerve, electromotive force in nerve, electrical fishes, and electromotive action in the eye, with a revision of section four of the fourth chapter of the first volume, dealing with secondary electromotive action in muscle.

No other book with which we are acquainted brings together in such philosophic form the numerous important facts which are to be found in these well-printed and well-bound volumes.

Clinical Lectures on Diseases of the Heart and Aorta. By George William Balfour, M.D., LL.D., F.R.C.P., F.R.S., Consulting Physician to the Royal Infirmary, Edinburgh, etc. Third Edition. London: Adam and Charles Black. 1898.

This volume is essentially a clinical one and is of the best type of such. In this the third edition much has been rewritten of the earlier editions and additions have been made, so that there are now some five hundred pages in the work. The treatment of the subject is easy and clear, the different chapters being presented in the form of lectures, of which there are seventeen. The opening lecture is an especially good one, on the diagnosis of cardiac disease with special reference to the symptoms and physical signs. Lectures two to nine discuss the various valvular lesions; lecture ten, some of the functional disorders of the heart, such as tachycardia, palpitation, bradycardia, etc. The secondary results of cardiac disease are well presented in the next lecture, and angina pectoris and other forms of cardiac pain in lecture twelve. Diseases of the heart other than valvular diseases form the subject matter of lecture thirteen, and the next lecture is devoted entirely to the subject of treatment. The final chapters embody the author's ideas on the subject of aneurism, a subject in which he is especially at home, having enjoyed an exceptionally wide experience in that line.

The book makes close reading, but the style is good and the mechanical get-up of the work is excellent.

Epidemic Cerebro-Spinal Meningitis and its Relation to Other Forms of Meningitis. A Report of the State Board of Health of Massachusetts. By Dr. W. T. Councilman, Dr. F. B. Mallory, and Dr. J. H. Wright. Boston. 1898.

In this contribution to scientific medicine the commonwealth of Massachusetts again shows her appreciative intelligence for the cause of true progress. This report is a model of its kind and is worthy of the highest enconiums, both to the authors and to enlightened legislative bodies that give occasion to such endeavors.

Atlas of Methods of Clinical Investigation, with an Epitome of Clinical Diagnosis and of Special Pathology and Treatment of Internal Diseases. By Dr. Christfried Jakob, former First Assistant in the Medical Clinic at Erlangen. Authorized Translation from the German. Edited by Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, Physician to the Philadelphia Hospital, etc. Philadelphia: W. B. Saunders. 1898.

The designation "atlas" in this instance is surely warranted in consideration of the fact that there are no less than one hundred and eighty-two colored illustrations and sixty-four pictures in the text. Unquestionably accurate illustrations aid greatly in the retention of clinical conditions and fix them better in the mind than mere descriptions can do. Supplementing the plates is an epitome arranged as a compendium to be used in conjunction with larger text-books. The author's words have received rather free translation at the editor's hands and an index has been added. No doubt this American reproduction will be well received by students and recent graduates.

The Middlesex Hospital. Reports of the Medical, Surgical, and Pathological Registrars for the Year 1896. London. 1897.

This report contains much interesting though not very get-at-able material. It consists for the most part of pages of abstracted histories and abstracts from the pathological reports. On the whole the report is of the statistical type.

The Extra Pharmacopœia. Revised in Accordance with the British Pharmacopœia, 1898. By William Martineale, F.L.S., F.C.S., Member of Council of the Pharmaceutical Society, and late Examiner. Serotherapy, Organotherapy, Medical References, and a Therapeutic Index, by W. Wynn Westcott, M.B., Coroner for North-East London. Ninth Edition. London: H. K. Lewis. 1898.

We are glad to welcome a new edition of this accurate and serviceable therapeutic manual. It contains notices of several drugs introduced into practice during the past three years; orrhotherapy and opotherapy are naturally more fully treated than in the eighth edition, and certain changes have been made to bring the work into accordance with the new edition of the British Pharmacopœia. We have commended the work so often that we have nothing to add further than to say that it maintains its excellence.

Rheumatoid Arthritis. Its Pathology, Morbid Anatomy, and Treatment. By Gilbert A. Bannatyne, M.D. Glas., M.R.C.P. Ed.; Hon. Physician to the Royal United Hospital, and to the Royal Mineral Water Hospital, Bath. Second Edition. Illustrated. Bristol: John Wright & Co. 1898.

In the new edition of this excellent monograph the author reaffirms, and with greater emphasis than before, his belief that this is a microbic affection, at least in its acute form; the chronic form being probably of a degenerative nature. The chapter on treatment is one that will afford great comfort to the reader who can inoculate himself with a little of the author's optimism. He believes that, so far from rheumatoid arthritis being incurable, "all cases, if recognized early, are curable, and if, in the later stages, not curable, yet the attack can be arrested, and further damage prevented."

Les Premiers Soins à Donner en Cas d'Accidents Subits. Conférences du Dr. Frédéric von Esmarch. Traduit par le Dr. Eugène Van Oye. Troisième Édition Française. Bruxelles: A. Manceaux. 1897.

This is a French translation of Esmarch's well-known and highly valued work on first aid to the injured. The original is recognized as a classic and a model for all treatises on this important theme.

Atlas of Legal Medicine. By Dr. E. Von Hofmann, Professor of Legal Medicine and Director of the Medico-Legal Institute at Vienna. Authorized Translation from the German. Edited by Frederick Peterson, M.D., Clinical Professor of Mental Diseases in the Woman's Medical College, New York; Chief of Clinic, Nervous Department, College of Physicians and Surgeons, New York. Assisted by Aloysius O. J. Kelly, M.D., Instructor in Physical Diagnosis, University of Pennsylvania; Adjunct Professor of Pathology, Philadelphia Poly-

clinic; Visiting Physician to St. Mary's and St. Agnes' Hospitals; Pathologist to the German Hospital, Philadelphia. Philadelphia: W. B. Saunders. 1898.

THIS is one of the well-known series of Lehmann's Medicinische Handatlanten. There are one hundred and ninety-three illustrations in black and fifty-six colored plates, each one with descriptive text. The atlas may be most profitably used as a complement to any of the standard works on medical jurisprudence.

YELLOW FEVER. Clinical Notes by JUST TOUATRE, M.D. (Paris), former Physician-in-Chief of the French Society Hospital, New Orleans; Member of the Board of Experts, Louisiana State Board of Health. Translated from the French by CHARLES CHASSAIGNAC, M.D., President New Orleans Polyclinic; Editor New Orleans Medical and Surgical Journal. New Orleans: New Orleans Medical and Surgical Journal, Limited. 1898.

ANY work dealing with tropical diseases is timely now, and especially is one treating of yellow fever. American sanitarians will soon have before them the Herculean task of removing the accumulated filth of centuries in Havana and other Cuban cities, and of exterminating the yellow plague which has so long battened upon it. Dr. Touatre's clinical description of yellow fever is graphic, and even the inexperienced should have little difficulty, with this book in hand, in recognizing a case of the disease. The rules and suggestions for treatment are sound and practical, and in the present state of our knowledge one will not err in following them. The book was written in French, as the author feared he had not sufficient mastery of English to trust himself in the use of it, but the translation leaves nothing to be desired, the French epigrammatic style being well preserved in correct and idiomatic English.

EPILEPSIA E CRIME. Par JULIO AFRANIO PEIXOTO. Bahia: V. Oliveira & C. 1897.

THIS is a graduation thesis for the degree of doctor of medicine at the Bahia (Brazil) Medical School, and is a well-digested review of the literature, chiefly French and Italian, of the subject.

DISEASES OF THE STOMACH. A Text-Book for Practitioners and Students. By MAX EINHORN, M.D., Adjunct Professor of Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Dispensary. Second Revised Edition. New York: William Wood and Company. 1898.

THE well-merited popularity of this work, which, without making invidious comparisons, may justly be called the best and most practical treatise in the English language on gastric affections, is shown by the necessity of a second edition within little over a year. The author has improved the opportunity to make the few alterations which the advances in this branch of medicine during the past twelve months have made advisable.

CHIRURGIE DE L'INTESTIN. Par M. JEAUNEL, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Toulouse. Paris: Institut de Bibliothèque Scientifique. 1898.

THIS is a fairly exhaustive treatise upon the surgery of the intestine. In his remarks upon anæsthesia, the author emphasizes the desirable qualities of chloroform in abdominal operations, though he recognizes the fact that ether is safer. The various intestinal sutures are described and discussed, and good diagrams of them are given. The descriptions and figures of the various intestinal operations are good. Especially good are the descriptions of methods of intestinal resection and suture, and among these we might specify that of the method of Maunsell, one which we rarely see clearly described. There is a long chapter upon preternatural anus, with diagrams of the different forms of that condition, and figures of the many instruments which have been suggested as useful in the treatment of it. This part of the work, as well as some others, would have easily stood a little condensation. The chapter on appendicular troubles is by no means up to date, and the author would learn much from an examination of the American literature upon this subject. The descriptions of the various methods of resecting the cæcum are satisfactory, and, as is the case throughout the work, the illustrations are good. On the whole, the book may be said to cover the field in a satisfactory manner.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-Sixth Annual Meeting, Held in Edinburgh, July 26, 27, 28, and 29, 1898.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 240.*)

GENERAL SESSIONS.

Third Day—Thursday, July 28th.

AFTER a busy morning in most of the sections, the third general meeting assembled in McEwan Hall on Thursday afternoon, to hear the address in surgery. Sir T. Grainger Stewart presided.

An Investigation of Blackwater Fever. — DR. SAUNDBY announced that he had a resolution to bring forward at the request of the section on tropical diseases. This resolution had been passed by the section quite unanimously, and was considered most important. It urged the government to send out an expert pathologist to investigate the subject of blackwater fever. The council agreed with the section, and he therefore proposed the adoption of the resolution at this general meeting of the association. The motion was seconded by Professor Chiene, and at once agreed to.

The Address in Surgery was then delivered by PROFESSOR ANNANDALE, regius professor of clinical surgery in the University of Edinburgh. The subject was "The Present Position of Surgery" (see page 208).

MR. THOMAS BRYANT, of London, moved, and PROFESSOR BENNET, of Dublin, seconded a vote of thanks, which was carried by acclamation.

Fourth Day—Friday, July 29th.

The fourth or concluding general meeting was held on Friday morning, when the

Address in Psychology was delivered by SIR JOHN BATTY TUKE, M.D., president of the Royal College of Physicians of Edinburgh (see page 209).

A vote of thanks for the address was moved by DR. BLANDFORD, seconded by DR. MACDONALD, of New York, and carried unanimously.

Then came the concluding business of the association, the usual votes of thanks for the manner in which local bodies and others contributed to the success of the meeting. This year the series of votes seemed more formidable than usual, but all were duly honored before the members scattered to take part in the garden parties and other entertainments, which were unexhausted and continued throughout the day, only to give place to the excursions on the day following.

The votes of thanks included the lord provost, magistrates, and council for the welcome in the McEwan Hall; the lord provost and Mrs. Thomson for their reception in the Museum of Science; the dean and chapel royal for the service in the cathedral, and Dr. Whyte for his sermon; the university for the use of the splendid buildings; the two royal colleges and the Medical Society; the Duke of Buccleuch, Marquis of Bute, Earl of Hopetown, and numerous others for hospitable entertainments; Lady Grainger Stewart for looking after the comfort of the ladies; the managers of the Royal Infirmary and other hospitals and public institutions. Even this list is hardly complete, but it expresses to some extent the obligations of the association. A cordial vote of thanks to the president, to which Sir Thomas briefly replied, wound up the proceedings.

SECTION ON TROPICAL DISEASES.

First Day—Wednesday, July 27th.

President's Address.—The session was opened with an address from the president, Dr. Patrick Manson, who drew attention at the outset to the remarkable progress which had been made during the last twenty years in our knowledge of diseases prevailing in the tropics. He said that since the discovery of the parasite of malaria by Laveran in 1880, the study of tropical medicine had become so extensive as to be in itself sufficient work for a lifetime, and consequently, like many other departments of science, was becoming day by day more specialized. Every year the volume of discovery increased, new fields of inquiry were constantly being opened up, and pathologists were beginning to realize the important fact that just as the fauna and flora of the tropics were infinitely richer in species than were those of the temperate zones, so the pathological fauna and flora of the tropics and the diseases to which they gave rise were also infinitely more numerous than their congeners of cooler climates. From a pathological point of view, therefore, he continued, there was abundant justification for the initiation of this section. As members of the special tropical section, his hearers had three distinct duties to perform. In the first place, they must work for the affiliation and organization of the five or six thousand British practitioners who, more or less directly, were interested in tropical practice. Secondly, they had to see that those who proposed to join their ranks in the future were properly educated in their special branch. All of them felt acutely the backward state of their educational system, in its bearing on tropical medicine, and they must insist upon its improvement. Lastly, they had to discuss the problems of tropical diseases. Though much had been done in recent years, that which had been accomplished had but served once more to show that there was no finality in research. Laveran's discovery had illuminated many things that were dark before, but it had also opened out new problems and shown dark spots of ignorance hitherto unsuspected. He had left untouched the practical aspect of that important subject, the etiology of malaria. Beyond that which the studies of Ross had revealed, which would be described in a paper to be read later, they still knew absolutely nothing of the malaria parasite as it existed outside the human body or of the exact physical conditions that caused it after months or even years to spring into active pathogenic life. Again, that other great tropical disease, or rather group of diseases, which they called dysentery, was still, as regarded many of its forms, their causes and their treatment, a sealed book. The pathology of liver abscess was still, as it had ever been, a *quæstio vexata*. They had just begun to know a little about the symptoms, epidemiology, and pathology of beriberi; they did not know its cause. Filariasis, ankylostomiasis, distomiasis, were all new subjects bristling with obscurities as well as with practical points in prevention and treatment. There was plenty of work for them to do. These were not a tithe of the problems of tropical pathology calling for consideration. Every one who had tried to work in that field must have felt dimly that the recognized and named diseases of the tropics were far outnumbered by the unnamed and undifferentiated diseases. In all pathology there was no such field for fruitful original research and discovery as tropical medicine. He hoped that the tropical section might become a permanent feature in the annual meeting of the association.

Unclassified Fevers of the Tropics.—The first subject for discussion in this section was the unclassified fevers of the tropics. This was opened by Brigade-Surgeon Lieutenant-Colonel Crombie, I.M.S., who gave a very full classification of tropical fevers as he had seen them, and described at considerable length their several forms, dwelling especially on those which were rather indefinite and therefore difficult to differentiate.

The discussion was taken part in by Dr. Sambon, Captain Hughes, Major Baker, Drs. Arnott, Thornkill, Cousland, and Cantlie. Most of the speakers seemed agreed that climatic fevers should be separated from malaria, and it was suggested that there was another class which might well be differentiated from either of the two. The general opinion seemed to be that the theory which attributed ardent fever to infection was not in accord with Indian experience.

The Habitat of Malaria.—Dr. Andrew Davidson then read a paper on the malarial problem in its epidemiological aspects, showing that the disease was by no means so restricted in its area as was sometimes supposed. Even in 66° N. latitude malaria was not unknown, and he gave some account of it as it occurred on the shores of the Gulf of Bothnia.

Dr. Manson remarked on the fact that pigment was found in a large percentage of normal lymphocytes, and he described the form in which it was found and the danger of confusing anatomical and pathological appearances.

Dr. Thin exhibited a specimen of a parasite from a case of pernicious fever in British Guiana which had been sent to him by Dr. Daniels.

Malarial Disease of the Eye.—Surgeon-Major Yarr, A.M.S., then read an important paper on malarial affections of the eye—a subject in which much interest was expressed, but which elicited no discussion.

Then came a more practical paper by Surg.-Maj. J. H. T. Walsh, I.M.S., on the "Clinical Aspects and Treatment of Malarial Fever."

Surgeon-Captain Buchanan, I.M.S., read a paper on "Cerebro-Spinal Fever as Seen in India."

Blackwater Fever.—Dr. Sambon described the ravages of this disease in tropical Africa, and said that he thought it was most likely a specific disease—probably allied to the hæmoglobinuria of cattle, and caused by a parasite classed between protozoa and bacteria. Dr. Sambon did not believe that it was merely an aggravated form of malaria, nor did he accept the recently propounded hypothesis that it was brought on by dosing with quinine.

The section adopted a resolution that this fever ought to be carefully studied on the spot by a commission of experts sent for the purpose. This resolution was ordered to be sent to the council of the association.

In connection with this subject, there was present a deputation of missionaries from the west coast of Africa, to urge the association to use its influence to induce the government to institute an inquiry into blackwater fever by means of experts sent for the purpose. A movement in this direction has already been taken at the request of the Blantyre and Livingstonian missions, as well as of the African Lakes Corporation, and Lord Salisbury has favorably responded and a conference has been held at the foreign office. In Northern Rhodesia and in Uganda the ravages of the disease have been felt by officers and sailors on the lakes, rivers, and coasts, and officials of the government and company, as well as by missionaries and planters. The strongest and healthiest young men continually fall victims to blackwater fever.

Dr. MacVicar reported that every week some European died of the disease. In the last nine months the Universities Mission had lost four men, and three others had been invalided home. He said that planters died off like flies with it, and he desired a well-equipped bacteriologist to be sent out for a year

or two or till he could elucidate the causes of the disease.

Dr. G. Smith, secretary of the Free Church Mission, said that both death and invaliding from blackwater fever were of constant occurrence in British Central Africa. Two years ago the committee sent out Dr. Ramsay and supplied him with bacteriological apparatus to investigate and report upon this fever. Unfortunately he had himself suffered from three attacks of it and had been obliged to return. He reports that there was urgent need of expert investigation.

The secretary of the African Lakes Corporation said that five of its employees had died since January —three of them from this form of fever—while another had been invalided from it. All four were young, strong, healthy men. In one year the deaths from this fever amounted to 5.42 per cent. of the whole European population, without taking into account those that were invalided home; while the most recent return showed that last year the mortality amounted to sixteen per cent. of the European residents.

With these facts before them, which were already known to most members of the section, no time was lost in the adoption of the resolution.

Second Day—Thursday, July 28th.

Dr. Patrick Manson, President, in the Chair.

Beriberi in Temperate Climates. — Dr. Conolly Norman, superintendent of the Richmond County Asylum, Dublin, read a paper with this title. Dr. Norman showed that beriberi had been met with in northern Germany; in Suffolk County Asylum, England; in the Richmond County Asylum, Dublin; in the States of Arkansas and Alabama, U. S. A.; and in Newfoundland during the last few years. The outbreak in Dublin, as in England, had been confined to pauper lunatics, but in Dublin several of the nurses in attendance had been attacked. The first appearance in Dublin was in 1894, when a severe outbreak occurred, and again a still more severe recrudescence took place in 1896–97. In all some five hundred and thirty-four cases had been recorded, with forty-four deaths. The cases under Dr. Conolly Norman's care in Dublin showed the typical symptoms and signs of beriberi as they occurred in tropical countries, and there could be no question as to the diagnosis. As to the mode of infection, no explanation of any kind could be given. Rice had been held as a possible source, but very little rice was consumed and there was no difference between the quality or kind of rice supply of the pauper lunatics and that used elsewhere in the city. Ling, a dried form of which was presumably obtained from Newfoundland, where the fishermen were known to suffer from beriberi, was also looked upon with suspicion. This fish was first used at the Dublin Asylum in 1894, the year of the outbreak, but no fish of the kind was being actually consumed previous to or at the time of the appearance of the disease. One patient, who had been in the asylum ten years, had, or was supposed to have had, beriberi in the far East in 1857. That this case should have caused an outbreak thirty-seven years subsequently to infection seemed improbable. In regard to the symptoms, Dr. Norman agreed with Grimm that there were an initial fever and a period during which the knee jerk was exaggerated. This was succeeded by absence of knee jerk, numbness and loss of sensation in the extremities, followed by tenderness on pressure, at times quite acute.

Dr. Manson said that by personal examination he had confirmed the diagnosis of beriberi in the cases mentioned by Dr. Norman. He thought that beriberi was not such a rare disease in temperate climates as was generally believed, and that a more accurate knowledge of the disease would in all probability dis close its presence more frequently.

Dr. Norman, in reply to questions put by Mr. Cantlie, stated that bacteriologic and microscopic examination of the blood gave negative results, and that the cases of what looked like permanent contractions in the limbs were prolonged but not permanent.

Dr. Osler, of Baltimore, said that beriberi was still prevalent in Newfoundland, and that a few cases found their way to the United States from Newfoundland as well as from the West Indies, Cuba more especially. He did not agree with Dr. Manson that a disease so pronounced in symptoms and epidemicity was at all likely to escape detection.

Pellagra.—Dr. Sandwith, of Cairo, read an abstract of a paper on this disease as met with in Egypt. He contended that the disease closely resembled the Italian variety and that it arose from the same cause —diseased maize. He objected to pellagra being considered a mere skin disease, and showed by a record of cases and by photographs that the cutaneous affection was only an expression of, or coincident with, the constitutional affection. Patients in time wasted, became depressed, and frequently ended their days in a lunatic asylum. The photographs exhibited showed clearly that the skin was affected only where directly exposed to the sun's rays. As regards treatment, Dr. Sandwith recommended rest, mixed diet, no maize, cod-liver oil, fresh bone marrow, baths, and emollients.

The Treatment of Acute Dysentery.—Dr. Sandwith then read a paper on this subject, which caused a keen discussion. He advocated enemata of various kinds, with sulphate of magnesium by the mouth in repeated doses.

Dr. Osler, of Baltimore, contended that the greatest objection to enemata in acute dysentery was the pain and exhaustion caused by their administration. To prevent the pain attending enemata in dysentery he found that previous application of cocaine was effective. He had used the double tube for washing out the rectum in preference to other methods. Ipecacuanha, although to be recommended in many forms of dysentery, was wellnigh useless in several—such as the amœbic form.

Dr. Bentley, of the Straits Settlements and Cairo, advocated the use of salol as an intestinal disinfectant.

Dr. Banne, of British Guiana, held that every case of dysentery had to be dealt with on its own merits; in some simple rest effected a cure, and in others salol, beta-naphthol, or alcohol proved advantageous.

Dr. Prentice stated that in Central Africa large doses of ipecacuanha were usually effective.

Surgeon-Major Davidson said that until the pathology of dysentery was better known, its treatment was necessarily empiric and had to vary with the individual case.

Brigade-Surgeon Lieutenant-Colonel Cromlie, of the Indian medical service, warned practitioners that not every case of intestinal flux with blood meant dysentery, and that many cases of catarrh with blood were classed as dysentery. He had found chloral, in gr. xx. dose, an excellent preliminary to the administration of ipecacuanha, which latter drug was in many cases highly efficient.

Sir Joseph Ewart, late of the Indian medical service, said he was astonished to hear ipecacuanha so lightly spoken of as a remedy in acute dysentery. He was in India when the drug was first introduced as a remedial agent, and by comparing the mortality statistics before and after ipecacuanha was used, he had learned how great the benefits had been and how immensely the death rate was lowered. Further, he believed that the timely use of ipecacuanha would prevent such sequels as liver abscess and chronic dysentery.

Unsanitary Environment the Cause of Yellow Fever and Bubonic Fever. — Inspector-General Turnbull, of the royal navy, presented a carefully worked out and instructive compilation of facts collected chiefly from naval records, and showed that environment and not infection was the cause of yellow fever.

The following papers were read by title: "A Leaf from the Early History of Bacteriological Discovery," by Dr. Andrew Smart, LL.D., vice-president of the section; "On the Training of Regimental Officers in the Prevention of Disease in the Army in Tropical Climates," by Capt. Louis Hughes, R.A.M.C.; "Surgery in the Tropics," by J. Cantlie, F.R.C.S., London.

Third Day—Friday, July 29th.

Dr. Andrew Davidson, Vice-President, in the Chair.

Plague.—Dr. Simpson read a paper on the plague in India. He paid a high tribute to the courage and devotion of medical men, European and native, in dealing with plague in India, and also to the nurses, native assistants, soldiers, and civilians who volunteered their help. Plague was not endemic to India, but was as much an importation there as it was in Europe. Hundreds of years sometimes intervened between recorded epidemics, and as had happened in India, so a recurrence might happen in Europe, for it was but little over two hundred years since plague visited Britain, and within that period recurrences on the continent had been many. The present virulent epidemic in India was not of the same nature as the plague commonly termed Levantine. The latter form was a dying form of the disease, but slightly inclined to spread, and marked by a small death rate. Plague had always shown a preference for the northwestern countries of India. It had been found, however, in Calcutta in former times, and it looked as though it might assume an epidemic form there soon. Dr. Simpson's statements went to show that Calcutta had a few cases in 1897, and again in 1898, when some one hundred and twenty-three persons had suffered. He believed that the Shropshire regiment, among whom a peculiar form of inguinal buboes prevailed, was infected with a form of pestis minor. This regiment had been on "plague duty" in Hong Kong during 1894, when plague was rife there, and both soldiers and civilians in Hong Kong for some time previous to the outbreak had been suffering from this affection. Dr. Simpson advocated a properly constituted sanitary service for India, and regretted that the offer of the Indian princes to found a research laboratory, with Professor Haffkine in charge, as a jubilee memorial, had not been acceded to.

Surgeon-Major Baker, of the Indian medical service, said he was favorably impressed with Haffkine's method of treatment. He insisted upon the absolute necessity for isolation and segregation; and with the value of floor disinfection in hospitals to prevent infection of the hospital staff. Disinfection of household effects before being handled and destroyed was necessary to prevent disease attacking the sanitary employees.

The Testing of the Plague Prophylactic in Plague-Stricken Communities in India.—This was a paper prepared for the meeting of the section by Professor Haffkine and Surgeon-Major Bannerman, of the Indian medical service. By numerous tables it was shown how the mortality had been reduced by inoculation with plague serum. A careful compilation of many experiments brought out the fact that the mortality among the protected as compared with the unprotected was lessened by eighty-six per cent.

Brigade-Surgeon Lieutenant-Colonel Arnott read an abstract of Surgeon-Captain Childe's contribution to the plague research committee on the "Pathology of Plague," and Brigade-Surgeon Lieutenant-Colonel Dimmock described the measures taken in Bombay to dispel the plague.

The Role of the Mosquito in the Evolution of the Malarial Parasite.—Dr. Patrick Manson, the president of the section, gave, by special request and with the permission of the secretary of state for India and of Surg.-Maj. Ronald Ross, of the Indian medical service, a lecture and exposition of the work done lately by the latter in the investigation of this subject. It was now over three years since Dr. Manson first promulgated a clear hypothesis as to the manner in which the mosquito removed the malarial parasite from the human body, and acted as its extracorporeal host. Not able to follow up the subject himself, Dr. Manson had found in Surg.-Maj. Ronald Ross a pupil endowed with keen scientific instinct, a firm believer in his theory, and a master of technique. To him Dr. Manson had set the task of working out and establishing the truth or otherwise of his views. To this, for three years, Ross had devoted himself with rare ability, and with the result that his investigations had placed us on the threshold of, if we had not already entered upon, one of the most important discoveries in the etiology of this or any other age. Up to the time Manson indicated the meaning to be attached to the evolution of the flagellated body outside the human body, observers were content with merely recording the differences of the various forms of the plasmodium. Since that important induction, however, the prosecution of the study had entered a new phase, and one which promised to lead to results of the greatest importance. Seeing that certain phases of the parasite developed into a flagellated body in the microscope field, some twenty minutes, more or less, after withdrawal from the body; seeing also that these flagella broke away and sought to enter other cells, Manson recognized in this an indication, if indeed he did not establish the fact, of the commencement of the extracorporeal life of the parasite. Beyond this, however, no clew was forthcoming as to how the parasite bred and continued its existence. It was at this stage that Manson propounded his mosquito theory and intrusted its elucidation to Ross.

The various stages of their work were arranged under several headings: (1) Ross found that the mosquito, in imbibing the human blood, ingested the parasite. (2) He saw the formation of the flagellated body in the blood in the mosquito's stomach. (3) He observed the flagella break away from the parent cell and attain a separate existence. Ross thereby established the probable correctness of the conjecture that in the mosquito the parasite entered a new stage of existence. To work out the behavior and development of the parasite in the mosquito was now the problem. After partial success with the human malaria, and for several reasons, Ross elected to investigate the problem in birds. Birds, the speaker said, suffered from intracorpuscular blood parasites like those in human malaria, and Labbé had shown that definite forms of parasites were frequent in Europe. Two species in particular he had described. They were known as Proteosoma and Halteridium; they were definite organisms, readily found by those experienced in this branch of parasitology in bird's blood. (4) Ross now allowed a particular species of mosquito (the gray mosquito) to feed on birds with Proteosoma in their blood, and soon discovered that the parasite entered with the blood the mosquito's stomach. (5) Examining his mosquitoes some hours later, he discovered certain oval pigmented bodies in the muscular coat of the mosquito's stomach. (6) By hundreds of obser-
